EPR studies of the isolated cofactor in the state reduced by dithionite, FeMoco (s-r) (i.e. semi-reduced) show that it retains the characteristic signal with spin 3/2 observed for the so-called 'M center' (which is in fact FeMoco inside MoFe protein). The broadening of the signal of the isolated FeMoco , compared with the signal of the M center, is attributed to a small change in the ligand sphere of the cofactor upon isolation. In the presence of added thiophenol the EPR signal returns to its form inside the protein apparently because S group of the thiophenol becomes the ligand of the Fe1 atom (instead of cysteine 275 SH group). The cyclic voltammogram of the cofactor on the glass carbon electrode in DMF shows that in addition to the process $\text{FeMoco}(\text{ox}) \rightarrow \text{FeMoco}(\text{s-r})$ at -0.32 V there is the reduction at -1.1 V with the corresponding oxidation at -0.9 V. These waves are ascribed by the authors [12] to the pair $\text{FeMoco}(\text{s-r})/\text{FeMoco}(\text{red})$.

When the Marcus theory of electron transfer was applied to electron transfer in nitrogenase, it was found that non-adiabatic theory is not applicable. It was therefore concluded that an event associated with either MgATP binding or hydrolysis acts to gate electron transfer between Fe protein and MoFe protein [13a]. The role of MgATP might be explained by the necessity to transfer electrons against the thermodynamic potential in the process of electron transfer from the Fe_4S_4 cluster of the Fe protein to the P-cluster of the MoFe protein to create particularly strong electron donor for FeMoco , although the mechanism of its action is not quite clear.

Recent investigations of electron transfer in the tight complex combining the Fe protein isolated from the bacterium *Clostridium pasteurianum* (Cp2) with the MoFe protein isolated from another bacterium *Azotobacter vinelandii* (Av1) demonstrated that primary electron transfer occurs within this complex even in the absence of MgATP and that the latter accelerates electron transfer more than 10 000-fold [13b]. Analysis of this effect shows that MgATP apparently shifts the redox potential of Fe protein (E_0) to a more negative value, therefore changing ΔE (difference in redox potentials of the electron donor and acceptor); this change alone is not, however, likely to be sufficient for the observed nucleotide-dependent rate acceleration. The important observation of this work is that Cp2Av1 is unable to transfer more than one electron to MoFe protein even when MgATP is present. This explains why Cp2Av1 complex is inactive towards any substrates of nitrogenase (even H_2 is not formed) because at least two electrons are required, even for such substrates as acetylene to produce ethylene, and protons to produce dihydrogen.

This supports the view that two electrons are transferred to P-cluster and the second electron requires probably very precise complementarity of the two proteins unattainable in the complex Cp2Av1. Perhaps the transfer of this second electron corresponds to particularly strongly negative value of redox potential.

In conclusion, it can be said that enzymatic reduction of dinitrogen requires substrate coordination on the polynuclear FeMo cofactor. To ensure catalytic reduction of the substrate the reduced cofactor is situated at a distance typical of

electron transfer (14 Å) from the P-cluster, which contains at least two electrons capable of being transferred to FeMoco. MgATP hydrolysis helps to increase the rate of electron transfer to the P-cluster and at least one electron is transferred from the Fe_4S_4 cluster against the thermodynamic potential presumably increasing the electron-donor properties of the P-cluster for subsequent transfer of electrons to MoFe cofactor. In their reduced states both are sufficiently strong reducing agents with redox potentials presumably more negative than -1 V. Using electrochemical terminology the P-cluster can be regarded as a 'nano-electrode' with the catalyst, FeMoco bound to it. It might be thought that the mechanism of catalysis for dinitrogen reduction is close to that for the 'optimum catalyst' considered above. The P-cluster and FeMoco might function in the coupled way in the most difficult stages of dinitrogen reduction in the coordination sphere of FeMoco. Accordingly it was shown that P-clusters are oxidized in a certain step when dinitrogen is reduced by nitrogenase [13a].

6.9 N_2 Reduction in Aprotic Media

Enzymatic dinitrogen reduction involves an electron donor, e.g. flavodoxin in vivo or dithionite in vitro (which we now know can be replaced by photoelectron donor), a system of electron transfer, and a site of dinitrogen activation, where the N_2 molecule is bound and subsequently reduced to ammonia with participation of protons. As we have seen, this site, evidently FeMoco, is itself a well organized molecular system which, in combination with the P-cluster, reduces N_2 by a mechanism of coupled one-electron and multi-electron transfer. If we can use a stronger reducing agent then the system for N_2 activation and reduction presumably need not be so well organized. In aprotic media we can use very strong reducing agents, although the reaction naturally cannot produce hydrazine or ammonia because of the lack of protons. At least stoichiometric reaction can be expected to break the NN bond and to form nitrides from intermediate N_2 complexes and then to produce ammonia upon subsequent addition of an acid.

Until the 1960s, however, dinitrogen was considered so chemically inert that no attempts had been made by investigators working with transition metal compounds in the presence of strong reducing agents to verify the possibility of N_2 reduction—dinitrogen gas was used as an inert atmosphere for conducting various reactions.

In 1964 Vol'pin and Shur published their paper [14] describing the results of dinitrogen reduction in aprotic media. The reaction turned out to be quite general. In the presence of different transition metal compounds, for example $CrCl_3$, $MoCl_5$, WCl_6 , $FeCl_3$, and $TiCl_4$, when N_2 under high pressure (100–150 atm) was reacted with strong reducing agents, for example $LiAlH_4$, $EtMgBr$, or $i-Bu_3Al$, ammonia was produced on acid decomposition of the products formed. The system $Cp_2TiCl_2 + EtMgBr$ ($Cp = \pi-C_5H_5$) in ether was found to be even more active towards N_2 —the yield of NH_3 (after hydrolysis) was 67 mol % with respect to Ti

compound even at atmospheric pressure and nearly quantitative at elevated N_2 pressures. The number of transition metal compounds and possible reductants was later greatly increased by Vol'pin et al. and also by other groups of investigators.

Apart from the compounds already mentioned, vanadium, manganese, and cobalt chlorides, tetra-alkoxy derivatives of titanium, acetylacetonates of V, Cr, Mo, Mn, and Ni, Cp derivatives of Zr and Nb, and triphenyl phosphine complexes of Ti and Fe were found to be active. Later lanthanide complexes were included in the list of dinitrogen-reducing systems, the most effective being compounds of samarium and yttrium.

The transition metals of groups IV, V and VI, particularly Ti, V, Cr, Mo, and W, have the strongest N_2 -reducing capacity. Ti compounds are particularly active. In the first row of transition metals, the ammonia yields decrease generally from left to right, in line with the decreasing stability of the metal nitrides. Co and Ni compounds are usually of low or no activity. Palladium, copper and platinum complexes have no activity in any system tested.

Yields of NH_3 (after hydrolysis) depend on the reducing agents. They include such strong reductants as organometallic compounds ($RMgX$, RLi , and R_3Al), metal hydrides ($LiAlH_4$ and LiH), free metals, and aromatic radical ions. Catalytic hydrogenation was not observed, but occasionally H_2 increased the yield of NH_3 (after hydrolysis) in combination with other reducing agents.

Catalytic reduction was, however, occasionally observed. $TiCl_4$ can catalyze the reduction of N_2 by aluminum metal in the presence of $AlBr_3$ at $130^\circ C$ and N_2 pressure of 100 atm. Yields of ammonia (after hydrolysis) usually vary from 0.01 to 1 mol mol $^{-1}$ transition metal compound, indicating that two transition metal atoms participate in the reduction of one N_2 molecule, although in some systems (particularly with very strong reductants) up to 2 mol NH_3 are produced per mol transition metal.

6.10 Dinitrogen Reduction in Protic Media

As has already been mentioned protic media are attractive for N_2 reduction, in particular because hydrazine or ammonia can be directly produced and the search for catalytic reduction is more promising. There is, however, an important obstacle—the strong reducing agent can be unstable in protic surroundings, readily producing dihydrogen:

The choice of the systems active to N_2 in protic solutions must, therefore, naturally be more limited than in aprotic media.

The first reproducible results demonstrating efficient dinitrogen reduction with participation of protons were reported in 1970 [15]. Table 2 lists systems reducing N_2 in the presence of water or methyl alcohol. They are mainly based on V^{II} and

Table 2. Systems reducing N₂ in protic media ($p_{\text{N}_2} \approx 100$ atm).

M	Reductant	$T(^{\circ}\text{C})$	Products	Yield (mol mol ⁻¹ M ⁻¹)
Ti ^{II} (d ²)	Na(Hg)	20	N ₂ H ₄ , NH ₃	0.01
V ^{III} (d ³)	V(OH) ₂ + Mg(OH) ₂			
	pH 14.3	20	N ₂ H ₄ , NH ₃	0.65
	pH 12	20	NH ₃	0.35
	V ^{II} + catechol, pH 10.5	20	NH ₃	0.75
Mo ^{III} (d ³)	Ti(OH) ₃	60	N ₂ H ₄ , NH ₃	1
	Ti(OH) ₃ + Mg(OH) ₂	110	N ₂ H ₄ , NH ₃	170
	Cr(OH) ₂	90	N ₂ H ₄ , NH ₃	0.80
	without Mo	90		0.015
	Na(Hg) ($p = 1$ atm)	20	N ₂ H ₄ , NH ₃	1700
	Eu(Hg) ($p = 1$ atm)	20	N ₂ H ₄ , NH ₃	26
Nb ^{III} (d ²)	Nb(OH) ₃	35	N ₂ H ₄ , NH ₃	0.09
Ta ^{III} (d ²)	Ta(OH) ₃	35	N ₂ H ₄	0.02

Mo^{III} compounds, although later Nb^{III}, Ta^{III} and Ti^{II} compounds were also included. It is clear that all the systems found so far are based on d² and d³ electronic configurations. They are active in alkaline solution and include mainly hydroxides, i.e. the systems are heterogeneous. There is also a unique family of homogeneous systems based on solutions of vanadium(II) complexes with catechols. One of the simplest and most effective heterogeneous systems is mixed V^{II}–Mg^{II} hydroxide. The reduction of N₂ occurs in aqueous or alcohol suspensions of freshly prepared hydroxide formed by adding excess alkali to the solution of a mixture of VCl₂ and MgCl₂. The reaction produces hydrazine and ammonia at high rates at room and lower temperatures and atmospheric N₂ pressure.

At high concentrations of alkali (pH 13–14) and high N₂ pressures hydrazine is mainly produced according to the stoichiometry:

At low alkali concentrations (pH 8–12) ammonia is produced directly from dinitrogen without intermediate formation of free hydrazine:

Freshly prepared mixed hydroxide contains vanadium(II) clusters reactive towards dinitrogen. Some indirect evidence indicates that the number of vanadium ions in the clusters activating dinitrogen approaches four or six. For example, introduction of other ions, such as V³⁺ inhibits N₂ reduction and quantitative analysis of the V³⁺ inhibition effect leads to the conclusion that tetramers are the likely species; tetramers are also suggested by analysis of ethane and ethylene formation in the reduction of acetylene.

Kinetic analysis of N_2 reduction shows that the reaction can be regarded as pseudo-homogeneous. Analysis reveals Michaelis–Menten dependence of the reaction rate on dinitrogen pressure. This enables estimation of the enthalpy of dinitrogen complex formation and the activation energy— $\Delta H = -4 \text{ kcal mol}^{-1}$ and $E = 8.4 \text{ kcal mol}^{-1}$. These values indicate that the intermediate complex is very unstable and highly reactive. Mixed V^{II} – Mg^{II} hydroxide is one system that disproves generally accepted views of dinitrogen as very inert molecule. N_2 can be very active in systems that are neither strong bases or acids nor very strong reductants or oxidants. The important condition for high chemical reactivity of N_2 is the possibility of accepting simultaneously at least four electrons by intramolecular electron transfer in an intermediate polynuclear complex including at least four atoms that are electron donors.

6.11 Soluble Complexes of Vanadium (II)

The exact structure of the intermediate vanadium(II) cluster in the mixed V^{II} – Mg^{II} hydroxide and in other hydroxides active towards N_2 is, of course, difficult to elucidate, and it was important to find a homogeneous system reducing N_2 in protic media. This was realized in 1972 with complexes of V^{II} with catechols or substituted aromatic diols and triols which were found to reduce N_2 efficiently in homogeneous water and alcohol solutions [16].

With unsubstituted catechol complexes in water the reaction proceeds in the pH range 8.5 to 13.5 with maximum yields at ca pH 10.5. For substituted catechols the pH range corresponding to the most active complexes reacting with N_2 differs noticeably (Table 3). Later the number of catecholate V^{II} complexes active towards dinitrogen was greatly increased but the family of the V^{II} complexes with aromatic diols and their relationship towards N_2 remain quite unique—no other complexes have yet been found that reduce dinitrogen in protic media, homogeneously, with reasonably high yields of products.

The reaction of N_2 with V^{II} catechol complexes in methanol occurs at room temperature and atmospheric N_2 pressure. The yield of NH_3 , which is the only reaction product, reaches ca 50 % relative to $V^{II} \rightarrow V^{III}$ oxidation. In aqueous so-

Table 3. Dinitrogen reduction by vanadium(II) complexes with aromatic ligands (L) (room temperature, $[V^{II}] = 0.05 \text{ M}$, $[L] = 0.5 \text{ M}$).

L	Solvent	p_{N_2} (atm)	Time (h)	Yield NH_3 (%)	$[NaOH]/[L]^a$ or pH ^b
Catechol	CH_3OH	1	0.03	47	1.14 ^a
Catechol	CH_3OH	15	0.17	75	1.14 ^a
Catechol	H_2O	100	1.5	60	10.5 ^b
Gallic acid	H_2O	100	4.0	48	12.9 ^b
Pyrogallol	H_2O	100	4.0	60	13.5 ^b

lutions such yields are observed only at elevated dinitrogen pressures. In the absence of N_2 a parallel reaction of V^{II} oxidation by the solvent protons proceeds with H_2 evolution. As N_2 pressure increases the yields of NH_3 increase and those of H_2 decrease. But even at the elevated pressure the yield of NH_3 does not exceed 75 % and does not increase when the N_2 pressure is increased further; 25 % of the electrons are used for H_2 formation. Thus, analogous to enzymatic reduction with Mo nitrogenase, the stoichiometry of the reaction at saturating N_2 pressure corresponds to the equation:

This equation including H_2 evolution *coupled* with the reduction of N_2 reflects the polynuclear character of the intermediate complex.

Acetylene is quantitatively reduced by V^{II} catecholate to ethylene with *cis*-deuteroethylene formed selectively from C_2D_2 , also similarly to enzymatic reduction of C_2D_2 by nitrogenase. Distinct from N_2 reduction, the pH range for the reduction of acetylene is much broader than for dinitrogen (from ca pH 5 to concentrated alkali solution). Kinetic studies of the oxidation of vanadium(II) catecholate complex by dinitrogen have led to the reaction equation:

$$-d[V^{II}]/dt = k_1[V^{II}]^2[N_2] + k_2[V^{II}]^{0.5}$$

The first term of the equation corresponds to the reduction of N_2 to NH_3 and the second to the parallel and *independent* evolution of H_2 formed from the solvent protons.

N_2H_4 which could be the intermediate in the reaction is easily and quantitatively reduced to NH_3 in V^{II} -catechol solutions. When N_2 reduction is stopped at its initial stages by addition of an acid or an oxidant (VO_2SO_4) a small quantity of N_2H_4 is found. A kinetic study of the reduction of specially added hydrazine revealed, however, that the rate constant is at least two orders of magnitude smaller than necessary for free hydrazine to be the intermediate producing ammonia. The results show that N_2H_4 is formed by decomposition of an intermediate by acid or oxidant; the intermediate, not being free hydrazine, seems similar to a vanadium hydrazine derivative. Similar results indicating intermediate N_2^{4-} derivative formation were obtained in enzymatic dinitrogen reduction. The second order of vanadium concentration in the rate equation for N_2 reduction, and at the same time the one-half order for H_2 formation, are indicative of the complex polynuclear structure. It is possible, for example, to assume that the active complex contains four vanadium atoms and two complexes are needed to reduce N_2 to NH_3 , whereas a dinuclear complex produced H_2 , and this dinuclear complex is formed in equilibrium dissociation of the tetramer into two dimers. In this case H_2 formation coupled with N_2 reduction could be explained assuming that after ammonia formation by the octamer, for which six vanadium atoms are required, a dimer of V^{II} is formed and this readily produces dihydrogen.

EPR spectra observed for the active complex at a pH of ca 10.5 led to the conclusion that the complex is trinuclear and that ammonia is formed when the trinuclear

Figure 4. The X-ray structure of vanadium di-*tert*-butyl catecholate complex [18].

clear complex coordinating N_2 reacts with another trinuclear complex, not containing N_2 , to produce two molecules of NH_3 by use of six vanadium electrons [17]. Although this mechanism did not explain the one-half order for (independent) formation of H_2 it was accepted in the paper [17] and in later reviews (e.g. Ref. [2]).

New important information about the structure of the intermediate complex was obtained from the X-ray studies of V^{II} complex with di-*tert*-butylcatecholate [18]. The complex, the structure of which is presented in Figure 4, contains four vanadium ions; two are divalent and two trivalent, but they are indistinguishable, thus their oxidation state is 2.5 and the complex can be regarded as existing in a *semi-reduced* state, similar to the s-r state of FeMoco in the presence of dithionite, which is not sufficiently reduced to activate dinitrogen.

The tetrameric vanadium complex contains also two sodium ions. Each is coordinated by two oxygen atoms of methanol molecules and by two oxygen atoms of different catechol molecules. Because of this coordination, oxygen atoms are μ_2 -bridging Na and V atoms. One of the three independent catechol molecules participates in the coordination of the vanadium atoms by one O only whereas the second atom is protonated and does not participate in the metal coordination. It is apparent that the complex

contains the core with two μ_3 -bridges formed by methanol OR groups. When all vanadium ions are in the V^{II} state in the form of the complex active to N_2 this

μ_3 -bridging OR group is probably loosely bound to three V^{2+} ions, and this core containing four V^{2+} ions most probably becomes the site activating N_2 in a complex of the type:

Ultimate intramolecular electron transfer from $4V^{2+}$ to N_2 will produce the hydrazido derivative, particularly on protonation of one of the four nitrogen atoms:

These findings prompted us to reconsider the results of EPR spectra and to make more profound analysis of kinetic data for N_2 reduction by catecholate vanadium(II) complexes. The conclusion was that a tetra-vanadium structure for the complexes is in a better agreement with the EPR spectra than a trinuclear structure; kinetic results also confirmed the tetranuclear structure of the complex [19]. We therefore regard the tetranuclear structure as confirmed for unsubstituted and substituted catecholate V^{II} complexes, at least for those so far investigated.

Thus the conclusion is that tetranuclear complexes are likely to be the active species in the reduction of N_2 to hydrazido derivatives, and then to hydrazine, by reaction with solvent in protic media, whereas octanuclear complexes (or transition states) are needed to transform N_2^{4-} species into two ammonia molecules.

6.12 Catalytic Dinitrogen Reduction

A catalytic system for dinitrogen requires the presence of a sufficiently strong reducing agent that would reduce the oxidized form of the catalytic complex (after reaction with N_2) to the initial reduced state. For example if we could reduce vanadium(III) complexes formed in N_2 reduction by vanadium(II) we would be able to create a catalytic system functioning with the chosen reductant. Finding such a strong reducing agent which is able to reduce V^{III} to V^{II} in *alkaline solutions* is, however, apparently difficult and H_2 is formed instead.

More likely candidates as catalysts from the data of Table 2 are molybdenum(III) complexes which activate N_2 to reduction only in the presence of a stronger reducing agent, such as $Ti(OH)_3$, $Cr(OH)_2$, or $Ta(OH)_3$. Presumably these strong reductants take part in the process, transferring electrons to molybdenum atoms

coordinating dinitrogen. Molybdenum(III) activates N_2 in a di- or polynuclear complex forming an intermediate of the type $Mo \equiv N \equiv N \equiv Mo$ which is unable to produce hydrazine or ammonia readily at the expense of Mo^{III} oxidation to Mo^V or Mo^{VI} . The reaction might become thermodynamically more favorable if a stronger reducing agent situated nearby simultaneously transfers electrons, reducing molybdenum to its initial Mo^{III} state. Therefore to reduce dinitrogen catalytically we might try to construct a system containing a bulk reducing agent which adsorbs the catalytic Mo^{III} complex at the surface and is an electroconductive material, in order to use the electrons from remotely situated atoms. For electrochemical reduction electrons from the cathode can be used if the catalytic complex is adsorbed at the surface of the electrode.

The first catalytic system based on this approach for N_2 reduction in protic media was realized with Mo^{III} as the catalyst and Ti^{III} hydroxide as the reductant [15]. With pure $Ti(OH)_3$ the yields of products of N_2 reduction in the presence of Mo^{III} formed in the process of co-precipitation of both metal hydroxides (or hydroxo complexes) by addition of alkali reaches only equimolar amounts with respect to molybdenum even at elevated temperatures and N_2 pressures. In the presence of salts of some other metals, e.g. Mg^{2+} , Ca^{2+} , or Sr^{2+} , in solution before the addition of alkali, the yields increase and the system becomes catalytic. The effect of magnesium salts was particularly pronounced. Yields of hydrazine and ammonia are increased and at sufficiently high temperatures and pressures reach several hundred turnovers per molybdenum. The highest yields are obtained when the ratio of Mg^{2+} to Ti^{3+} is 1:2. At this ratio a compound of formula $MgTi_2O_4$ is produced and forms fine crystals, as was revealed by X-ray analysis and electron microscopy. The catalytic effect of Mo^{III} is observed when the complexes of molybdenum(III) are adsorbed on the surface of $MgTi_2O_4$. Accordingly, whereas for stoichiometric reduction with mixed hydroxides it is essential to have both metals present in homogeneous solution before addition of alkali, for catalytic reduction $MgTi_2O_4$ can be formed initially without molybdenum. After subsequent addition of the molybdenum compound catalytic activity towards N_2 is observed.

The magnesium–titanium compound $MgTi_2O_4$ has semiconducting properties, and evidently the molybdenum complex with coordinated dinitrogen forms an electron trap on the surface. Dihydrogen is rapidly evolved in the absence of N_2 , particularly at high temperatures. Introduction of molybdenum even in very small amounts compared with titanium strongly inhibits H_2 evolution in the presence of N_2 . Evidently Mo complexes are adsorbed at the active sites of $MgTiO_4$, preventing electron flow to the H_2 evolution centers. The dependence of the reaction rate on N_2 pressure is Michaelis in form, which enables estimation of the equilibrium constant for dinitrogen complex formation and the rate constant for N_2 reduction in the complex. The temperature dependence of the constants gives a value of -7 kcal mol^{-1} and -17 e.u. for the enthalpy and entropy of complex formation; the activation energy, E , for N_2 reduction in the complex is 20 kcal mol^{-1} [20].

It can be mentioned that a titanium(III) compound was recently found [21] to be an efficient electron donor for the Fe_4S_4 cluster in Fe protein of nitrogenase and can therefore be used in N_2 enzymatic reduction.

6.13 Catalytic Dinitrogen Reduction by Amalgams

The mechanism proposed for the catalytic reduction of N_2 by an electroconductive reductant has prompted the use of amalgams as reducing agents. Amalgams such as those formed by sodium and europium are sufficiently strong reductants (redox potentials -1.84 and -1.4 V, respectively) and at the same time they are reasonably stable in contact with water or alcohol. The amalgams can be prepared electrochemically by use of a mercury cathode and passing electron current through the solution containing metal ions; they can, therefore, be used for the electrochemical reduction of dinitrogen.

Introduction of the sodium amalgam has increased the yield of the reduction products, N_2H_4 and NH_3 , in the catalytic system based on Mo^{III} and $MgTi_2O_4$ described above. Obviously the amalgam transfers electrons through $MgTi_2O_4$ to the Mo^{III} catalytic complex and prevents titanium(III) oxidation. It is clear that if conditions could be found under which the catalytic complex were bound directly to the surface of the amalgam, an electron-conducting material such as $MgTi_2O_4$ would be unnecessary.

We found these conditions by introducing surface-active materials to a solution of a specially prepared catalytic complex containing molybdenum and stabilized by magnesium ions [22]. The structure of the complex which was isolated from the solution in its oxidized form is presented on Figure 5 [23]. When it is reduced to the Mo^{III} state the complex becomes an active catalyst of dinitrogen reduction to hydrazine and ammonia by sodium amalgam. Phospholipid (phosphatidylcholine)

Figure 5. The X-ray structure of the anionic part of the octamolybdenum complex [23].

Figure 6. Proposed mechanism of dinitrogen reduction catalyzed by octamolybdenum(III) complex incorporated in the phospholipid film on the amalgam surface.

and also polyvinyl alcohol, both surface-active materials, were found to strongly increase the reaction rates and the products yields.

The yields were found also to increase in the presence of phosphines, particularly trimethyl or tributyl phosphine. After all the improvements of the catalyst and reaction conditions the system became by far the most active of known non-biological catalytic systems for the reduction of dinitrogen at ambient temperature and pressure. The specific activity (the rate of N_2 reduction per mole of the complex) reached and even exceeded that of nitrogenase. Up to 1000 turnovers relative to the molybdenum complex can be observed at atmospheric pressure and more than 10 000 turnovers at elevated N_2 pressures.

The role of the surface-active materials, e.g. phosphatidylcholine, is to form a thin film on the surface of the amalgam, with the catalyst incorporated and thus bound to the surface of the electron donor (Figure 6). With phosphatidylcholine the film is kept at the surface because of attachment of the positive phospholipid heads to the negatively charged surface. Electrons are transferred from the amalgam to the catalytic complex in the process of catalytic reduction. Similarly to the function of the P-cluster in nitrogenase the electron donor participates not only in the initial reduction of molybdenum in the catalytic complex to the Mo^{III} state but also during subsequent steps of substrate reduction. We can therefore speak of 'reductive coaction' of the donor in the process of N_2 reduction, according to the mechanism described in previous sections.

If the complex is reduced to the Mo^{III} state and there is no external electron donor in the system (the amalgam is removed) there is no reduction of dinitrogen, even stoichiometric, confirming the mechanism in which the reducing agent participates directly, in a coupled manner, in the reduction of the substrate which is co-ordinated by the catalytic complex.

More evidence for the participation of the reductant in the catalytic process is the dependence of the rate on the redox potential of the reductant. The reduction rate for the europium amalgam (redox potential -1.4 V compared with -1.84 V for sodium amalgam) is approximately two orders of magnitude smaller than for

Figure 7. Dependence on induced potential of the rate of formation of ethylene by reduction of acetylene [25]. The catalyst: octamolybdenum cluster (8.5×10^{-6} M); the reductant: Zn amalgam (2 %, w/w); the cocatalyst: thiophenol (4.7×10^{-3} M); $T = 20^\circ\text{C}$; $p_{(\text{C}_2\text{H}_2)} = 100$ mm Hg.

Na(Hg). The dependence of the rate of reaction for acetylene reduction by the Zn amalgam on the induced potential is shown in Figure 7. It is apparent that the dependence follows the Tafel law: $\ln v = A + \alpha E$ (here v is the rate and E is the induced potential).

This dependence was also found for electrochemical reduction of dinitrogen. As has been mentioned, the structure of the catalytic complex presented in Figure 4 corresponds to its oxidized form (Mo^{V} and Mo^{VI}). Unfortunately no crystals suitable for X-ray analysis were obtained for the Mo^{III} state of the complex, but there is evidence that in the reduced state the complex still contains 8Mo and 2Mg. It is possible that on reduction of the complex to the Mo^{III} state the structure becomes less rigid and some coordination sites become open to coordinate N_2 .

6.14 FeMoco as Catalyst for the Reduction of Nitrogenase Substrates at Amalgam Surfaces

As we have already seen, FeMo cofactor of nitrogenase is a polynuclear complex of composition Fe_7MoS_9 (homocitrate), and all the available evidence implies it is the active site at which dinitrogen and other nitrogenase substrates are activated and reduced. Yet despite its first isolation in 1977 the catalytic activity of FeMoco was detected only in 1997, i.e. 20 years later.

One possible reason for this is that, according to the mechanism described above, the cofactor must function in a coupled manner with electron transfer from the

P-cluster which is situated close to FeMoco. Presumably attempts to use it as a catalyst outside the MoFe protein had been made earlier with such reductants as NaBH_4 which functions as a separate entity only during collisions, i.e. comparatively rarely. As has already been mentioned, in FeMoco iron atoms probably co-ordinate dinitrogen activating it to further reduction. No iron complexes have yet been synthesized which function as catalysts for N_2 reduction in protic media, although several iron complexes reducing dinitrogen in *aprotic* media are known (e.g. Ref. [2]). Presumably such complexes will be prepared in the future, but meanwhile in the light of the catalytic mechanism described above it was natural to investigate the catalytic activity of the FeMo cofactor itself on the surface of multi-electron donors such as amalgams.

It was, indeed, found that FeMo cofactor in solution in DMF and NMF is an active catalyst for reduction of acetylene and other nitrogenase substrates by zinc, europium, and sodium amalgams [24, 25]. The reaction proceeds on the surface of the electron donor, thiophenol functions as a cocatalyst, not only as the proton donor but evidently also the cofactor ligand connecting it, in particular, with the surface of the amalgam. Some of the properties of the isolated cofactor, for example formation of ethylene and ethane from acetylene, inhibiting action of carbon monoxide, dihydrogen evolution, etc. are similar to those of the cofactor inside the protein, in particular, when the cofactor is bound to proteins of N_2 -fixing organisms different from that from which FeMoco was isolated. Dinitrogen was found to inhibit acetylene reduction by europium amalgam in the presence of FeMoco, the inhibitive effect being *quantitatively identical* with that observed in the reduction catalyzed by nitrogenase (Figure 8) [26]. The conclusion can therefore be drawn that the catalytic action of FeMoco is similar to that of synthetic molybdenum(III) complexes bound to the surface of the amalgam. To be catalytically active FeMoco

Figure 8. Inhibition of acetylene reduction by dinitrogen in protein and non-protein systems with FeMoco as catalyst, $p_{(\text{C}_2\text{H}_2)} = 10$ mm Hg. ■, isolated FeMoco with Eu amalgam as a reductant [26]; ●, nitrogenase from *A. vinelandii* (wild type) [27]; ◆, mutant DJ540 [28]; ○, wild-type MoFe protein [28].

must be bound to a multi-electron donor (such as amalgam or cathode in electrochemical reduction) and to be open to an acid with a certain pK which ensures synchronous protonation and electron transfer. To reduce dinitrogen it seems to be necessary to have a sufficiently strong acid to protonate the substrate but not to destroy the catalyst, which is less stable than synthetic catalysts in the presence of acids.

If both conditions are fulfilled (the presence of a reducing agent in close vicinity to FeMoco and a proton-donating substance of an appropriate pK) FeMoco can be catalytically active outside the MoFe protein.

In conclusion, it may be said that to achieve catalytic reduction of dinitrogen in both enzymatic and purely chemical systems in protic media it is essential to unite a one-electron reductant and a polynuclear catalyst activating dinitrogen in a single system such that they function in a coupled manner—one-electron transfer from the external reducing agent must be coupled with poly-electron transfer inside the polynuclear catalyst containing the substrate. Hopefully further development of this field along the lines of this mechanism will lead to new active catalytic systems reducing dinitrogen.

7 Transition-metal Complexes as Models of the Active Sites of Hydrogenases*

Cameron E. Forde and Robert H. Morris

7.1 Hydrogen Chemistry

7.1.1 Introduction

Controlling the movement of electrons and protons is vital to life and a variety of biologic systems have evolved with this purpose. Certain enzymes have the ability to separate the protons and electrons of dihydrogen and to harness the energy of this molecule to the synthesis of more complex molecules. Dihydrogen is the simplest molecule and yet the enzymes used to activate it (or to produce it) are amazingly complex. Part of the complexity of hydrogenase enzymes extends from the wealth of oxidation and protonation states of the active site metal cluster. This is due in part to the variety of interactions between dihydrogen and transition metals. While the ability of certain metals to evolve dihydrogen when exposed to acid or even water has been known for a long time, the ability of metals to form hydrides and subsequently the existence of 'non-classical' hydrides or dihydrogen complexes of the metals are more recent discoveries. Long before chemists proposed that dihydrogen forms complexes with transition metals, enzymes had been making use of transition metals to activate dihydrogen.

The chemistry of model systems of hydrogenase enzymes has developed along with the study of the enzymes. Developments in the characterization of the enzyme have spurred the development of model systems that provide a better understanding of the function of the enzyme. Ultimately, a complete understanding of the chemistry of the hydrogenase enzymes will require the synthesis of both areas of study. In this review we consider the work that has been done to characterize the enzyme, focussing on the areas that are amenable for study using model systems. We then

* Portions of this work appeared in the Ph. D. thesis of Cameron E. Forde, University of Toronto, 1997.

consider the model systems that shed light on the spectroscopic properties, the function and the structure of the hydrogenase enzymes. The work on theoretical models is then presented with a view toward a fuller understanding of the enzymes and the development of better models. In order to place the chemistry of hydrogenase enzymes and model systems in the context of known metal hydride and dihydrogen chemistry, we present a brief summary of these fields first.

7.1.2 Metal Hydride Chemistry

The properties of metal hydrides vary a great deal and depend to a large extent upon the metal. For example, the interactions between hydrides and alkali or alkaline earth elements tend to be ionic in nature while more covalent interactions are observed between hydride ligands of later elements (e.g. tin). For the transition metals the M–H bond strength increases going from 3d to 4d to 5d metals. The M–H bond strength is also influenced by the *trans* ligand. That is, the M–H bond is destabilized by high *trans*-influence ligands such as hydride or alkyl. The reactivity of metal hydrides can be described in terms of their ability to transfer a hydride (hydricity) [1] or their ability to transfer a proton (acidity) [2]. The hydricity is higher for the early transition elements with electron-donating ligands.

Transition metal hydride complexes are often highly fluxional. This feature is often reported for polyhydride complexes. An example of this is the report of the solid state and solution structures of the series of the iron group metals $[\text{MH}_3\text{L}_4]^+$ where L is either PMe_3 or PEt_3 [3]. These complexes can adopt a six-coordinate dihydrogen hydride or a seven coordinate trihydride conformation. The dihydrogen hydride conformation can exist in *cis* or *trans* configurations while the trihydride conformation can adopt a tricapped tetrahedral or a classical *cis*-trihydride arrangement. Variable temperature NMR spectra were used to determine the activation parameters for the fluxional processes. The relative stabilities of these different geometries for iron and ruthenium have been determined using *ab initio* calculations [4, 5].

Protonation of a metal hydride is one of the routes by which metal dihydrogen complexes can be formed. Addition of a proton to a hydride is a more facile process than the addition of a proton to a metal. This is due to the greater electronic rearrangement required to protonate a metal center than that required to protonate a hydride ligand. This feature of metal hydrides is a kinetic effect: the ultimate fate of the nascent dihydrogen complex is determined by thermodynamics. Depending upon the relative stabilities, the dihydrogen ligand can oxidize the metal center forming a dihydride, remain coordinated to the metal, or detach from the metal as $\text{H}_2(\text{g})$.

7.1.3 Metal Dihydrogen Chemistry

The physical properties of dihydrogen are well understood. Free hydrogen gas has a bond length of 0.74 Å, with a bond strength of 103 kcal mol^{−1}. The potential of proton reduction is set at 0 V for the normal hydrogen electrode (NHE) under

standard conditions (pH 0, 25 °C). This potential is pH dependent and a potential of -414 mV is calculated for pH 7 according to the Nernst equation. This equation also reveals that as the concentration of dihydrogen decreases from saturation the potential will rise. There is thus a range of potentials over which dihydrogen can be formed depending upon the conditions.

The first stable dihydrogen complex reported was $\text{W}(\text{H}_2)(\text{CO})_3(\text{PPr}^i_3)_2$ [6]. Several hundred stable dihydrogen complexes have been reported since this initial report and several reviews have appeared covering the synthesis, properties and reactivity of dihydrogen complexes [7–9]. The majority of the transition metals form stable dihydrogen complexes. Of interest with respect to the chemistry of hydrogenase enzymes are the dihydrogen complexes of nickel and of iron. There are numerous iron dihydrogen complexes but only one nickel complex has been reported. The nickel(0) complex $\text{Ni}(\text{H}_2)(\text{CO})_3$ is formed by photolysis of $\text{Ni}(\text{CO})_4$ in a hydrogen matrix at low temperature [10]. If the hydrogenase enzymes make use of nickel dihydrogen interactions then much of the chemistry of these enzymes has no precedence in the current literature. We attribute the lack of stable nickel dihydrogen complexes to the reduced ability of nickel to participate in stabilizing π -back donation with the dihydrogen ligand. Iron is better able to form stable dihydrogen complexes as its d-orbitals are higher in energy and able to stabilize the interaction with dihydrogen. More iron dihydrogen chemistry is discussed later in the section on modeling.

There are two components of the bonding interaction between a dihydrogen ligand and a transition metal. The interaction between dihydrogen and a transition metal is described as having $\sigma(\text{H}_2)$ -to- $\sigma(\text{metal})$ and $\pi(\text{metal})$ -to- $\sigma^*(\text{H}_2)$ components. The extent of the σ -donation is controlled by a variety of factors including the metal and the oxidation state as well as the ancillary ligands, especially the ligand *trans* to the H_2 ligand. The π -back-donation contribution confers stability, though homolytic cleavage results from too much back bonding. A positive charge on the metal enhances the σ -interaction with dicationic complexes with dihydrogen *trans* to a π -acid ligand being particularly strongly bonded [11].

The H–H bond length increases upon coordination to a metal center. The H–H separation in a dihydrogen complex can be determined by a number of techniques. Neutron diffraction yields this value directly, though there is a need to correct for the vibrational motion of the ligand [12]. X-ray crystallography is a less useful technique because of the poor X-ray scattering characteristics of the dihydrogen ligand. An NMR method is commonly used to correlate the spin–lattice relaxation time with the H–H bond length [13, 14]. The motion of the dihydrogen ligand has an effect on the relaxation time and two H–H separations are calculated for each of the two regimes depending upon whether the rotation of the dihydrogen moiety is greater or less than the spectrometer frequency. It is not uncommon for the rotational frequency of the dihydrogen ligand to be greater than 500 MHz! Another NMR technique to probe the H–H separation relies on the determination of the coupling constant between hydrogen and deuterium observed in the analogous HD complex. The H–D coupling constant decreases with a linear correlation from that of the free HD gas (43.2 Hz [15]) as the separation between the nuclei increases. These methods are quite useful for characterizing diamagnetic model complexes but

have limited applicability to the characterization of any H_2 ligands that might be present in an enzyme containing paramagnetic centers.

The acidity of a dihydrogen molecule increases upon coordination. The pK_a decreases from 35 for free H_2 gas (we find that in THF it is greater than 46 with pK_a $HPCy_3^+$ at 9.7) as a function of the metal and its oxidation state as well as the ancillary ligands. A very wide range of pK_a values has been reported for transition-metal dihydrogen complexes. There are now several examples of dihydrogen complexes with pK_a values below zero. The acidity of dihydrogen complexes of the d^6 transition metals can be estimated [16]. This method is applicable to the dihydrogen complexes of iron(II). The predictive powers of this method demonstrate that the properties of a dihydrogen ligand are influenced by the ancillary ligands. This is a direct result of the ability of ancillary ligands to influence the electrochemistry of the metal center.

The effect of the metal center on the properties of the dihydrogen ligand has been probed for the series of complexes $trans-[M(H_2)H(R_2PCH_2CH_2PR_2)_2]^+$ ($M = Fe, Ru, Os$; $R = Ph, Et$) [17]. These dihydrogen complexes are formed by protonation of the dihydride precursor compounds. The stretching frequency of the terminal hydride (ν_{M-H}) is found to increase down the period while the H–H separation in the dihydrogen ligand is approximately the same for iron and ruthenium but is greater for osmium. The lability of the dihydrogen ligand as judged by the H/D exchange properties increases from Os to Fe to Ru.

The ligand *trans* to the dihydrogen ligand is found to have a profound effect on the properties of the dihydrogen ligand. An early report compared the effect of chloride versus hydride in the series $trans-[Ru(H_2)X(R_2PCH_2CH_2PR_2)_2]^+$ ($R = Ph, Et$) [18]. The H–H separation in the dihydrogen ligand is longer when the *trans* ligand is chloride than hydride. This is attributed to the fact that chloride has a weak ligand field. Therefore the t_{2g} π -bonding d-electrons are higher in energy and back-donate more strongly into the σ^* orbital of the dihydrogen ligand.

An experimental report of the effect of the ligand *trans* to dihydrogen confirmed these theoretical results. The acidity of a series of ruthenium and osmium complexes, $trans-[M(H_2)XL_2]^{n+}$ ($L = Ph_2P(CH_2)_3PPh_2$; $X = CO, Cl, H$) has been determined [19]. The complex $[Ru(H_2)(CO)(dppp)_2]^{2+}$ is highly acidic with an estimated pK_a of -6 .

The effects of the *trans* ligand on the acidity of some dihydrogen complexes of ruthenium and osmium with the general formula $trans-[M(H_2)L(H_2PCH_2CH_2PH_2)_2]^{n+}$ have been quantified using density functional theory [20]. The ligand, L , affects the stability of the dihydrogen ligand as well as the stability of the conjugate base hydride, both of which influence the acidity of the dihydrogen complex. Ligands which destabilize the dihydrogen ligand while stabilizing the conjugate base hydride complex will lead to the most acidic dihydrogen complexes. The effect can be broken down in terms of the role of the ligand as a sigma donor and either a π -acceptor or π -donor. Strong sigma donor ligands (like hydride or alkyl) destabilize the conjugate base hydride and result in less acidic dihydrogen complexes. Strong π -donating ligands stabilize the dihydrogen ligand and destabilize the conjugate base hydride resulting in a less acidic dihydrogen complex. The most acidic dihydrogen com-

plexes result when the *trans* ligand is a strong π -acceptor ligand. Such a ligand stabilizes the conjugate base hydride and destabilizes the dihydrogen ligand. This result is of importance to the chemistry of hydrogenases as the strong π -acceptor ligands CN and CO are implicated as discussed later.

The effects of the ancillary ligand, L, on the M–H₂ bond dissociation energy in the chromium, molybdenum and tungsten complexes, ML(CO)₄(H₂), have been determined using ab initio calculations [21]. In this report it was found that the stability of the dihydrogen ligand increases when L is a strong σ -donor ligand while strong π -accepting ligands weaken the metal–dihydrogen bond. Conversely, the degree of activation of the dihydrogen ligand increases when the number of π -accepting ligands is reduced.

The dihydrogen ligand is often considered to be a highly labile ligand that interacts only transiently with metals. This perception is due in part to the properties of the Kubas complex that is only stable in an atmosphere of dihydrogen. Indeed, there are many other examples of highly labile dihydrogen ligands. However, this is not to say that all dihydrogen ligands are readily displaced from metal centers. The substitution of dihydrogen from *trans*-[Fe(H₂)H(dppe)₂]⁺ by a neutral ligand (MeCN, PhCN, or DMSO) is an example of a dihydrogen ligand which is difficult to displace [22]. In this case the kinetic and activation parameters support a mechanism in which one arm of one of a chelating diphosphine ligand opens up a coordination site for attack of the neutral ligand.

7.2 Hydrogenase Enzymes

7.2.1 Introduction to Hydrogenase Enzymes

Hydrogenases (EC 1.12.2.1) are enzymes that catalyze the two-electron oxidation of dihydrogen as well as the reduction of protons to form H₂. A given hydrogenase enzyme is optimized either for H₂ uptake or H₂ production, though there is also an example of a bidirectional hydrogenase (*Clostridium pasteurianum* hydrogenase I). The function of a given hydrogenase enzyme (H₂ uptake as opposed to H₂ forming) is determined by the physiological conditions like pH and factors inherent to the enzyme such as the co-factors that are present. These enzymes are found in lower life forms (archaebacteria, bacteria, and algae) and exist in both soluble and membrane-bound (both periplasmic and cytosolic) forms. With the exception of the H₂-producing methylenetetrahydromethanopterin dehydrogenase [23], all hydrogenases are metalloenzymes with redox-active iron–sulfur clusters and an active site metal cluster where H₂ is either consumed or formed. The metal content is used to subdivide the hydrogenase enzymes into three categories: iron-only [Fe], iron–nickel [FeNi] and iron–nickel–selenium [FeNiSe]-hydrogenases. These three categories of hydrogenase enzymes are distinct, though the [FeNiSe]-hydrogenase enzymes exhibit more resemblance to the [FeNi]-hydrogenases than they do to the [Fe]-hydrogenase

enzymes. The majority of hydrogenase enzymes are of the [FeNi] variety and these have also been the most studied. The hydrogenase enzymes have a number of interesting properties that have been modeled in a number of ways. In order to put the model chemistry into context we will present the properties of these enzymes in this section before considering the model systems in the following section.

Several recent reviews cover the model chemistry of [FeNi]-hydrogenases. The role of nickel in the active site of [FeNi]-hydrogenases has been reviewed [24]. This report concludes that a redox active role for the nickel ion in [FeNi]-hydrogenase enzymes is not supported by the current model chemistry. The involvement of cysteine ligands and/or the iron center is proposed to account for the redox activity of [FeNi]-hydrogenase enzymes. The nickel thiolate model chemistry is the subject of another review that raises the possibility of the involvement of nickel(I) hydrido complexes in the catalytic cycle of [FeNi]-hydrogenase [25]. The chemistry of nickel thiolate model complexes has been reviewed in order to elucidate the preferred oxidation state and coordination chemistry of nickel with relevance to the active site of [FeNi]-hydrogenases [26]. Nickel is known to take on a variety of roles in biology and these roles have also been reviewed [27–29].

The hydrogenase enzymes are very complex and a number of techniques have been used to probe the properties of these enzymes. Part of the complexity of hydrogenase enzymes is due to the different redox and protonation states in which the enzymes can exist. The presence of a variety of protonation and redox states is to be expected from enzymes whose function is to turn protons into dihydrogen (or vice versa). The existence of multiple redox and protonation states greatly complicates studies of the enzyme. The different redox states of the enzyme were first identified in relation to the different EPR signals that are observed. In the next section we consider the EPR evidence about the active sites of [Fe]-, [FeNi]- and [FeNiSe]-hydrogenase enzymes. A system of nomenclature to describe these various redox states will be developed in this section. We then present results of the oxidative and reductive titrations that have been reported to characterize the different redox states. Another useful technique used to characterize hydrogenase enzymes is infrared spectroscopy. A number of signals are observed for these enzymes that are not normally associated with protein samples. This section is rounded out with a description of some of the other techniques that have been used to explore the properties of the active sites of hydrogenases. After having presented the spectroscopic characterization we present the experiments that have been reported on the characterization of the function of these enzymes. We end our discussion of hydrogenase enzymes with the solid state structural characterization of the [FeNi]-, [FeNiSe]- and [Fe]-hydrogenase enzymes.

7.2.2 Spectroscopic Characterization of Hydrogenase Enzymes

Electron paramagnetic resonance

One of the techniques that have been used extensively to characterize hydrogenase enzymes is electron paramagnetic resonance. There are several paramagnetic

Table 1. Some examples of the EPR parameters observed for the various states of [FeNi]-hydrogenase enzymes from different sources.

centers in the various metal-containing hydrogenases. Of interest to this work are the EPR signals associated with the active site. The active sites of the hydrogenase enzymes exist in different redox and protonation states, some of which give rise to EPR signals. Different EPR signals are observed for the [FeNi]-, [FeNiSe]-, and [Fe]-hydrogenases. There are also other states that are not redox active and in the case of the [FeNi]-hydrogenases, we will present these states in the discussion of the infrared properties below.

The active sites of [FeNi]-hydrogenases give rise to a number of interesting EPR spectra. There are three EPR active states labeled **A**, **B** and **C**. Each of these states produces a rhombic EPR spectrum. Data for a variety of different [FeNi]-hydrogenases are collected in Table 1. These signals have been assigned to the Ni ion on the basis of ⁶¹Ni-labeling studies [30].

The [FeNi]-hydrogenase from *Desulfovibrio gigas* was studied by electron spin echo envelope modulation (ESEEM) spectroscopy in the **A** and **C** states [36]. The two states differ in their solvent accessibility as determined by exchange with solvent deuterons. The **A** state is solvent inaccessible while the **C** state is solvent accessible. Coupling to a ¹⁴N nucleus is observed in both states. The solvent accessibility of these two states has been confirmed by ENDOR spectroscopy. This study reveals two types of exchangeable proton species in the **C** state [37]. One of these protons interacts less strongly with the paramagnetic center and is consistent with a bound water or hydroxide ligand. The second proton species interacts more strongly and is not consistent with assignment as a hydride. This ligand is possibly a dihydrogen ligand or an agostic interaction. Oxidation of the **C** state produces the **B** state which retains only one exchangeable proton species. This species has a smaller coupling consistent with a water or hydroxide ligand. A comparison of these three states using Q-band pulsed ENDOR on ⁵⁷Fe and natural-abundance Fe [FeNi]-hydrogenases

from both *D. gigas* and *D. desulfuricans* reveals that the non-protein bridge present in the A state is broken in the other two states [38]. This work also assigns the oxidation states of the active site metal ions in the A state as [Fe(II)Ni(III)] where the iron ion is low spin, $S = 0$.

The active sites of [Fe]-hydrogenases exhibit different EPR spectra than the [FeNi]-hydrogenases. An early study of [Fe]-hydrogenase enzymes from *Desulfovibrio vulgaris* (Hildenborough), *Megasphaera elsdenii*, and two from *Clostridium pasteurianum* revealed that these enzymes exhibit signals due to $[4\text{Fe-4S}]^+$ clusters in their reduced state and more complex signals when oxidized [39]. These authors conclude that the active site of all four have S greater than 0 and integer, which in the oxidized state is exchange-coupled to an $S = 1/2$ species, most likely a low spin Fe(III) center.

The active sites of the [Fe]-hydrogenases from *Megasphaera elsdenii* and *Desulfovibrio vulgaris* (Hildenborough) have been investigated with one- and two-dimensional pulsed EPR spectroscopy [40]. The presence of a nitrogen-containing ligand was detected in the active sites of both enzymes. Unusual quadrupole values suggest a non-protein source for these nitrogen-containing ligands, consistent with cyanide ligands. The presence of an imidazole ring from a histidine residue is also suggested based on these EPR measurements, and this residue is likely part of a proton shuttle.

Infra-red absorption spectroscopy

The infrared spectra of hydrogenase enzymes exhibit absorbances in a region that is not normally associated with protein samples. This region, $1900\text{--}2100\text{ cm}^{-1}$ is more commonly associated with molecules with triple bonds. As we will see later this absorption can be attributed to carbonyl and cyanide ligands at the active site. In this section we consider the evidence from infra-red absorption spectroscopy as it pertains to the active sites of hydrogenase enzymes. Once again, we present the work on [FeNi]-hydrogenases and then the [Fe]-hydrogenases.

Studies of the infrared spectra carbon monoxide inhibited forms of [FeNi]-hydrogenase revealed that the native protein exhibits absorbances at energies not normally associated with protein samples. These absorbances in the $1900\text{--}2100\text{ cm}^{-1}$ region are also observed in [Fe]-hydrogenase samples. This absorption is attributed to the cyanide and carbonyl ligands at the active site metal centers. Cyanide and carbon monoxide are not commonly found as ligands to metal centers in metalloproteins. The different redox states of the enzymes give rise to different absorption spectra.

Exposure of the [FeNi]-hydrogenase from *Chromatium vinosum* to carbon monoxide produces a band in the infrared spectrum at 2060 cm^{-1} [41]. A shift to 2017 cm^{-1} is observed when ^{13}CO is employed. This band is in addition to the three bands at 2082, 2069 and 1929 cm^{-1} that are attributed to the native cyanide and carbonyl ligands. The two weak bands in the region $2040\text{--}2100\text{ cm}^{-1}$ are separated by $12\text{--}16\text{ cm}^{-1}$ and the separation of the average of these weak bands from the strong band shifts according to the state of the enzyme [42]. Labeling studies, using

Table 2. Infrared absorption wavenumbers in the range of 1900–2100 cm^{-1} associated with various states of the active site of the [FeNi]-hydrogenase enzymes from *C. vinosum* and *D. gigas*.

^{15}N or ^{13}C , and chemical analyzes have implicated one carbon monoxide molecule and two cyanide groups [43].

In the case of the [FeNi]-hydrogenase of *Desulfovibrio gigas* IR absorption in the 1900–2100 cm^{-1} region has been assigned for each of the redox-active states [44]. These data are collected in Table 2. This study revealed the presence of an EPR silent state labeled SU that exists as a mixture of two protonation states. The changes in IR properties have been used to determine the electrochemical potentials required for the changes in redox state. These data are presented in the following section.

The unusual IR properties of [FeNi]-hydrogenases are shared by the [Fe]-hydrogenases [46]. Analysis of the spectra of the [Fe]-hydrogenase of *D. vulgaris* obtained under a variety of redox conditions strongly indicate that [Fe]-hydrogenases contain a low-spin Fe ion in the active site with one CN group and one CO molecule as intrinsic, non-protein ligands [47].

Electrochemical titrations

Reductive titrations of the [FeNi]-hydrogenase from *Chromatium vinosum* were performed by variation of the H_2 -partial pressure [48]. Changes in the redox state of the active site were monitored by loss of the EPR signal. The reduction potential of the active site exhibits a pH dependence of $-60 \text{ mV (pH unit)}^{-1}$. This dependence suggests that the reduction of the active site is coupled with protonation.

The electrochemical potentials of different states of the [FeNi]-hydrogenase enzyme from *D. gigas* have been probed using oxidative titrations at pH 8.0 [49, 50]. In addition to the redox events of the iron-sulfur clusters the data are best fit to a model involving four different active site redox states between 0 and -400 mV . The potentials of these four redox states are collected in Table 3.

Table 3. Mid-point reduction potentials (mV relative to the NHE) reported for [FeNi]-hydrogenase enzymes under the given conditions.

Organism	A-SU	B-SI	SI-C	C-R	pH/T	Ref.
<i>C. vinosum</i>	-115	-115	nr	nr	8.0/30	48

<i>D. gigas</i>	-210	-135	-365	-430	7.7/40	44

nr = not reported

The periplasmic [Fe]-hydrogenase from *Desulfovibrio vulgaris* (Hildenborough) exists in two different catalytic forms: as isolated the protein is O₂-insensitive; upon reduction the protein becomes active and O₂-sensitive [51]. EPR-monitored redox titrations reveal a single reduction of the active site at a potential of -307 mV, just above the onset potential of H₂ production.

Other techniques

Two techniques that are particularly useful in the characterization of hydrogenase enzymes are Mössbauer and X-ray absorption spectroscopies. At low temperature (4.2 K), the [3Fe-xS] cluster exhibits a paramagnetic Mössbauer spectrum typical for oxidized [3Fe-xS] clusters. At higher temperatures (greater than 20 K), the paramagnetic spectrum collapses into a quadrupole doublet with parameters magnitude of δ EQ magnitude of -0.7 ± 0.06 mm s⁻¹ and δ = 0.36 ± 0.06 mm s⁻¹, typical of high-spin Fe(III). The observed isomer shift is slightly larger than those observed for the three-iron clusters in *D. gigas* ferredoxin II [52] and in *Azotobacter vinelandii* ferredoxin I [53] and may indicate a different iron coordination environment. When *D. gigas* hydrogenase is poised at potentials lower than -80 mV (relative to the normal hydrogen electrode), the [3Fe-xS] cluster is reduced and becomes EPR-silent. The Mössbauer data indicate that the reduced [3Fe-xS] cluster remains intact, i.e. it does not interconvert into a [4Fe-4S] cluster. Also, the electronic properties of the reduced [3Fe-xS] cluster suggest that it is magnetically isolated from the other paramagnetic centers [54].

X-ray absorption spectroscopy is a useful technique to probe the ligand environment of the nickel ion at the active site. Early EXAFS experiments using the NiK-edge on the [FeNi]-hydrogenase from *Thiobacillus roseopersicina* in the C state suggested the involvement of an unusual nickel-iron cluster [55]. When these studies were extended to compare the three EPR active states (A, B and C) and two EPR silent states (SI and R) no significant change in the edge energy is observed [56]. The data are best fit to a model involving six-coordinate nickel with a mixture of N/O- and S-donor ligands. Similar results are obtained for the [FeNi]-hydrogenase from *Alcaligenes eutrophus* in the as-isolated A state [57]. Upon reduction a model with four S-donor ligands with a Ni-S distance of 2.19 Å is appropriate. The incorporation of an iron atom in accordance with the crystallographic results (vide infra) improves the fit of the model to the data. However, the EXAFS technique is limited

in that it is difficult to distinguish between S and Fe scattering atoms at distances greater than 2.4 Å.

7.2.3 Hydrogenase Function

The function of a hydrogenase enzyme is either to produce H_2 or to oxidize H_2 . The [FeNi]-hydrogenases, in general, function as H_2 -uptake enzymes, though there are examples of [FeNi]-hydrogenases that evolve H_2 (e.g. *Pyrococcus furiosus*). Another generalization that can be made is that [Fe]-hydrogenase enzymes are 10 to 100 times as active as the [FeNi]-hydrogenase enzymes. However this greater activity comes at the price of greater oxygen sensitivity. While [FeNi]-hydrogenases are deactivated to varying extents by exposure to oxygen, [Fe]-hydrogenases are irreversibly deactivated by oxygen. The [FeNiSe]-hydrogenases are much less sensitive to exposure to oxygen.

Different patterns in the pH dependence of hydrogenase activity have been observed with enzymes purified from different species of *Desulfovibrio*. With the cytoplasmic hydrogenase from *Desulfovibrio baculatus* strain 9974, the pH optima in H_2 production and uptake were respectively 4.0 and 7.5 with a higher activity in production than in uptake. This contrasts with the periplasmic hydrogenase from *Desulfovibrio vulgaris* (Hildenborough). In this case the highest exchange activity was near pH 5.5. The periplasmic hydrogenase from *Desulfovibrio gigas* has the same pH optimum in the exchange (7.5–8.0) as in the H_2 uptake. The ratio of H_2 to HD production is greater than one for the first of these enzymes and below one for the latter two enzymes [58]. The absolute activities cannot be compared due to the effect of enzyme concentration on both the H_2 -uptake and H_2 -evolution assays [59].

7.2.4 Structural Characterization of Hydrogenase Enzymes

The structural characterization of hydrogenase enzymes has clarified much of the mystery that had surrounded the active sites of these enzymes. The report of the crystal structure of the [FeNi]-hydrogenase from *D. gigas* [60] revealed that the active site of this enzyme contained nickel and a second metal later identified as iron (PDB 1frv and 2frv) [45]. The nickel ion is coordinated by four cysteine residues. Two of these residues form a bridge to the iron ion. The second reported structure also contains a third bridging ligand that these authors suggest is most likely hydroxide. No other protein-based ligands coordinate these metals, though the iron ion has three other ligands that were modeled as water in the original structure. The later structure model used two cyanide ligands and one carbon monoxide ligand.

A second [FeNi]-hydrogenase structure, from *Desulfovibrio vulgaris* (Miyazaki F), revealed a similar active site cluster (PDB 1h2a) [61]. Like the structure of the *D. gigas* enzyme, the active site cluster consists of a nickel ion coordinated by four cysteine residues, two of which form a bridge to the iron ion. The iron ion has three nonprotein ligands that are proposed to be the diatomics S=O, CO and CN mole-

cules. In this case the third bridging atom is proposed to be sulfide as hydrogen sulfide (0.37 equiv.) is released on incubation under H_2 in the presence of cytochrome c3 or methylviologen [62]. The X-ray crystal structure of the reduced form of *D. vulgaris* (Miyazaki F) [FeNi]-hydrogenase reveals an overall structure that is very similar to that of the oxidized form, with the exception that the third monatomic bridge is absent, leaving this site unoccupied [63]. The coordinates of one other structure, the [FeNi]-hydrogenase enzyme from *D. fructosovorans*, have been deposited (PDB 1frf).

The single crystal X-ray diffraction structure of the [FeNiSe]-hydrogenase from *Desulfomicrobium baculatum* in the reduced, active form has also been reported [64]. The active site metal cluster is similar to those of the [FeNi]-hydrogenases reported with some interesting differences. The most obvious difference is the presence of a selenocysteine residue in place of one of the terminal cysteine residues. The reduced active site of *D. baculatum* has a nickel-iron distance that is 0.4 Å shorter than in the oxidized *D. gigas* enzyme. Like the reduced *D. vulgaris* enzyme, the bridging ligand is absent in the reduced *D. baculatum* hydrogenase.

The structures of two [Fe]-hydrogenase enzymes have also been reported. The structure of the [Fe]-hydrogenases from *Clostridium pasteurianum* reveals that the active site H-cluster of the enzyme is composed of a typical [4Fe-4S] cubane bridged via a cysteine thiolate to a binuclear Fe center (PDB 1feh) [65]. The structure of the [Fe]-hydrogenase from *Desulfovibrio desulfuricans* reveals this same arrangement (PDB 1hfc) [66]. These two crystal structure reports differ in their assignment of the bridging ligands of the two iron atoms of the binuclear cluster. The structure of the binuclear cluster from *C. pasteurianum* is reported to have two sulfides and one carbon monoxide as bridging ligands. In place of the sulfide bridges the binuclear cluster from *D. desulfuricans* is modeled with a bridging 1,3-propanedithiol molecule. The iron atoms are modeled as having octahedral coordination geometries with carbonyl or cyanide molecules. The presence of an iron moiety with CO and CN ligands in all types of hydrogenases suggests that this functional unit is incorporated for its ability to activate dihydrogen [66].

The structure of the CO inhibited form of the [Fe]-hydrogenase from *Clostridium pasteurianum* has also been reported (PDB 1c4c) [67]. The structural characterization indicates the addition of a single molecule of carbon monoxide. Carbon monoxide binds to an iron atom of the binuclear iron center at the site of a terminally bound water molecule in the native state (PDB 1c4a).

7.3 Modeling with Transition-metal Complexes

7.3.1 Introduction

We have shown in the previous section that there are a number of unusual properties of hydrogenase enzymes. In this section we present the work that has appeared in the literature toward modeling these unusual properties. As we will see there are a number of cases where the development of model systems has led to a greater

understanding of the enzyme. That is, after all, the goal of making model complexes. In the following presentation of model systems we will focus on the ways in which the model chemistry provides an improved understanding of the hydrogenase enzymes.

The presentation of the modeling of the hydrogenase enzymes is divided into four sections based on the aspect of the hydrogenase enzyme that is being modeled; spectroscopic, structural, functional and theoretical modeling. Spectroscopic models attempt to reproduce the unusual spectroscopic features that characterize the hydrogenase enzymes. These include EPR, IR and electrochemical properties. The structural aspects of the enzyme active site have been modeled through attempts to synthesize a complex or cluster with similar coordination environments as the enzyme active site. This type of modeling is usually assessed based upon the ability to reproduce metrical parameters such bond lengths or angles. The abilities of the enzymes to convert protons to dihydrogen (or vice versa) and to catalyze the exchange of H^+/H_2 comprise the functional aspects of the enzyme system that have been modeled with transition metal complexes. Theoretical techniques have also been employed to better understand the chemistry of hydrogenase enzymes. In the following sections we present the work on each of these types of modeling systems.

7.3.2 Spectroscopic Modeling

Many spectroscopic models have focussed on reproducing the unusual EPR properties of the different paramagnetic states of the active sites of the hydrogenase enzymes. Model chemistry should be instrumental in determining the coordination geometry and oxidation state of the paramagnetic center. As we mentioned above, the nickel ion has been implicated as the source of the EPR signals of the active site and model chemistry has focussed on monomeric nickel complexes.

The Ni(III) complexes of *N*-mercaptoacetylglucyl-L-histidine and *N*-mercaptoacetylglucylglycylglycine clearly show the rhombic EPR pattern and *g* values similar to the Ni(III) chromophore of hydrogenases [68]. These results suggested that the Ni(III) center of hydrogenases contains one cysteine sulfur coordination as equatorial ligand in a tetragonal geometry. In addition, an axial nitrogen ligand and a sulfur-rich Ni(III) site, as in an S4 donor set, were thought to be ruled out.

A number of model systems have attempted to reproduce the anomalous IR spectra of [FeNi]-hydrogenases. Initial efforts focussed on cyanide, carbon monoxide and nitric oxide complexes as these ligands are known to absorb in this portion of the infrared spectrum [69].

Some iron and nickel cyanide and carbonyl complexes have been reported as models of the [FeNi]-hydrogenase enzymes. The preparation and structures of the trigonal bipyramidal nickel and iron complexes with the tetradentate ligands tris(2-phenylthiol)phosphine (PS3) and tris(3-phenyl-2-thiophenyl)phosphine (PS3*) have been reported [70, 71]. The nickel carbonyl complex $[\text{Ni}(\text{PS3}^*)(\text{CO})]^{2-}$ exhibits ν_{CO} at 2029 cm^{-1} compared with the value of 1940 cm^{-1} for the iron carbonyl complex $[\text{Fe}(\text{PS3}^*)(\text{CO})]^{2-}$. Both of these complexes lose CO upon oxidation. The use of cyanide in place of carbon monoxide allows for the preparation of both $[\text{Fe}^{\text{II}}(\text{PS3})(\text{CN})]^{2-}$ and $[\text{Fe}^{\text{III}}(\text{PS3}^*)(\text{CN})]^-$ complexes. The IR properties of

Table 4. Selected IR properties of some carbonyl and cyanide complexes of nickel and iron with the PS3 and PS3* ligands [70, 71].

Complex	ν_{CN}	ν_{CO}
$[\text{Ni}^{\text{II}}(\text{PS3}^*)(\text{CO})]^{2-}$	na	2029
$[\text{Fe}^{\text{II}}(\text{PS3}^*)(\text{CO})]^{2-}$	na	1940
$[\text{Fe}^{\text{II}}(\text{PS3})(\text{CN})]^{2-}$	2070	na
$[\text{Fe}^{\text{III}}(\text{PS3}^*)(\text{CN})]^{-}$	2094	na
$[\text{Fe}^{\text{II}}(\text{PS3})(\text{CN})(\text{CO})]^{2-}$	2079	1904
$[\text{Fe}^{\text{III}}(\text{PS3})(\text{CN})(\text{CO})]^{-}$	2108	2006

these complexes are collected in Table 4. Addition of carbon monoxide to $[\text{Fe}^{\text{II}}(\text{PS3})(\text{CN})]^{2-}$ produces the six-coordinate complex $[\text{Fe}^{\text{II}}(\text{PS3})(\text{CN})(\text{CO})]^{2-}$ where the cyanide ligand remains *trans* to the phosphine. This latter complex can be oxidized electrochemically and increases in both ν_{CN} and ν_{CO} are observed.

The work of Darensbourg et al. has superseded these early model systems. A series of model compounds with the core unit $\text{Fe}(\text{CO})_2(\text{CN})$ or $\text{Fe}(\text{CO})(\text{CN})_2$ were found to reproduce the unique IR absorption spectra of [FeNi]-hydrogenases very well. The IR spectrum of the [FeNi]-hydrogenase enzyme from *D. gigas* in the A state exhibits bands at 1947, 2093, and 2083 cm^{-1} . The IR spectrum of the iron(II) model complex K $[\text{CpFe}(\text{CO})(\text{CN})_2]$ in acetonitrile exhibits absorption bands at 1949, 2094, and 2088 cm^{-1} which are assigned to the ν_{CO} , the symmetric ν_{CN} and the asymmetric ν_{CN} , respectively. The energies and peak-widths at half-maximum of this absorption are sensitive to the oxidation state of the iron center, to the medium and to the counter-ion. Polar media produce broad bands with peak width at half-maximum of the ν_{CO} band of 17 cm^{-1} in water. The use of non-polar solvents is required to achieve the narrow (4 cm^{-1}) peak width at half-maximum observed for the enzyme.

In spite of their structural and amino acid sequence differences, Fe-only and Ni-containing hydrogenases achieve the same catalytic reactions. A chemical modification of histidine residues using a highly specific reagent (pentaammineruthenium II) has been carried out on *Desulfovibrio vulgaris* Hildenborough Fe-hydrogenase and *Desulfovibrio desulfuricans* Norway Ni-Fe-Se-hydrogenase. The preliminary results suggest the existence of a general mechanism involving histidine residues in the two groups of hydrogenases. These residues may be part of the histidine-containing motive shown to be present in both Fe- and Ni-Fe-hydrogenase sequences by Hydrophobic Cluster Analysis. This analysis suggests a functional role for the small subunit of *Desulfovibrio vulgaris* Hildenborough [Fe]-hydrogenase [72].

7.3.3 Functional Modeling

As mentioned in the introduction, the addition of acid, or in some cases even water (e.g. the alkali metals), to metals can result in the evolution of hydrogen. The

potential role of nickel dihydrogen complexes in metal-containing hydrogenases was proposed early in the history of hydrogenase literature [73]. The report of a nickel(II) complex that produces dihydrogen electrochemically was later reported [74]. This was followed by a report of the production of dihydrogen by protonation of a nickel(I) complex [75]. However, the key to modeling the active sites of hydrogenase enzymes requires the ability to do more than evolve dihydrogen. Ideally what is needed in a successful model is the ability to not only evolve dihydrogen but also to activate dihydrogen. In this section we present the work on the model systems that mimic the function of hydrogenase enzymes.

One interesting model system incorporates nickel(II) into the rubredoxin protein scaffold [76]. Rubredoxins are electron-transport proteins with a redox-active mononuclear iron center coordinated by four cysteine residues. The nickel-substituted rubredoxin evolves H_2 and HD when exposed to D_2 . This system is much less active than the native enzymes with activities less than an order-of-magnitude below [FeNi]- and [FeNiSe]-hydrogenases. The ratio of H_2 to $H_2 + HD$ initially produced is used as an indicator of the mechanism. The Ni-rubredoxin model system has ratios in the range 0.45–0.60. Values of this ratio around 0.3 are indicative of heterolytic cleavage of the D_2 unit while values closer to 1 support a homolytic activation mechanism. Like the hydrogenase enzymes, the model system is inhibited by carbon monoxide. The concentration of CO required for 50 % inhibition is similar to that required for [Fe]-hydrogenase from *D. vulgaris* but much lower than that required for 50 % inhibition of the [FeNi]-hydrogenase enzymes.

Model systems that couple H_2 oxidation with the reduction of a cofactor have been reported. The complex Cp^*L_2RuH catalyzes the reduction of NAD [77] or methyl viologen [78] under dihydrogen. This system demonstrates that a ruthenium model system can catalyze the activation of hydrogen without the benefit of the protein scaffold.

An iron(II) hydride model system presents the possibility that protonation can occur at the cyanide ligand [79]. The site of protonation in the complexes $trans\text{-}FeH(CN)(R_2PCH_2CH_2PR_2)_2$ is controlled by the nature of the substituents R of the chelating diphosphine ligands. When the substituents are ethyl groups the site of protonation is the hydride ligand and the stable dihydrogen complex $trans\text{-}[Fe(H_2)(CN)(Et_2PCH_2CH_2PEt_2)_2]^+$ is formed. When the substituents are phenyl groups the site of protonation is at cyanide forming the hydrogen isocyanide ligand in the complex $trans\text{-}[Fe(H)(CNH)(Ph_2PCH_2CH_2PPh_2)_2]^+$. This variation in reactivity is attributed to the greater electron-donating ability of the alkyl-substituted phosphine ligands. The presence of more electron-donating ethyl groups results in a more basic hydride and thus a less acidic dihydrogen complex. Presumably the less electron-donating phenyl groups result in a dihydrogen complex that is more acidic than the corresponding hydrogen isocyanide ligand.

Two very acidic iron(II) dihydrogen complexes have been reported that have either carbonyl or hydrogen isocyanide ligands [11]. The complexes $trans\text{-}[Fe(H_2)(L)(Ph_2PCH_2CH_2PPh_2)_2]^{2+}$ ($L = CO, CNH$) are prepared by addition of triflic acid to the hydrido complexes $trans\text{-}[FeH(CO)(Ph_2PCH_2CH_2PPh_2)_2]^+$ or $trans\text{-}FeH(CN)(Ph_2PCH_2CH_2PPh_2)_2$. The short H–H separations in these dihydrogen complexes, as determined by NMR methods, suggest that there is very little back donation from the metal to the H_2 unit. Some degree of back-donation

has been thought to be necessary for the stabilization of the metal–dihydrogen interaction.

The analogous ruthenium and osmium complexes [80, 81] demonstrate similar reactivity. The series of complexes $\text{trans-[M(H}_2\text{)(CN)L}_2\text{]}^+$ and $\text{trans-[M(H}_2\text{)(CNH)L}_2\text{]}^{2+}$, where M = Fe, Ru, Os and L = bidentate phosphine, are prepared by protonation of the hydrido precursor complexes using triflic acid. The ruthenium complexes are the least stable and the dihydrogen ligand dissociates and is replaced by the triflate anion. The exposure of $\text{trans-[Ru(OTf)(CNH)L}_2\text{](OTf)}$ to 1 atm H_2 results in the elimination of triflic acid and produces a mixture of $\text{trans-[Ru(H}_2\text{)(CN)L}_2\text{]}^+$ and $\text{trans-[Ru(H)(CNH)L}_2\text{]}^+$ with the ratio of these two complexes being controlled by the electronic nature of the bidentate phosphine ligands. As mentioned above for the analogous iron complexes, the more electron-donating phosphine donor ligands stabilize the formation of the dihydrogen complex while the hydrido analog is favored by less electron-donating phosphine ligands.

One of the intriguing features of hydrogenase enzymes is their ability both to activate and to produce dihydrogen at neutral pH. This feature suggests that there is a hydrido species that can be protonated at neutral pH, or in other words a dihydrogen species with a $\text{p}K_{\text{a}}$ near 7. The ability of metals to lower the $\text{p}K_{\text{a}}$ of dihydrogen from 35 in the gas was discussed in the section on dihydrogen chemistry. There are other sites of potential protonation that must be considered. Two examples of such sites are the cysteine thiolates and the cyanide ligands at the active site. Protonation of ligands in the coordination sphere alters the properties of the active site. For example the protonation of thiolato donors results in an increase in the lability of this ligand [82].

7.3.4 Structural Modeling

Several reports have been published of complexes that model the binuclear active sites of [FeNi]-, [FeNiSe]- and [Fe]-hydrogenases. Most of these efforts have focussed on reproducing the metrical parameters that have been reported for the corresponding enzyme. Initially efforts centered on modeling a tetrathiolato nickel center thought to be the active site of [FeNi]-hydrogenases. The revelation that the active site is an iron–nickel heterodimer has prompted revision of the models. Much of the nickel thiolate model chemistry through 1995 has been reviewed [24–26] and in the following section we will focus on recent results that model the known binuclear active sites. Efforts to model the heterodimeric nickel–iron center will be presented first followed by the di-iron model complexes.

A nickel–iron complex is formed from the reaction of the nickel(II) complex of the tetradentate ligand *N,N'*-diethyl-3,7-diazaanonane-1,9-dithiolate with $\text{Fe(CO)}_2(\text{NO})_2$ [83]. The carbonyl ligands on the iron are displaced and the thiolato donors assume a bridging mode leaving two terminal nitrosyl ligands about the four-coordinate iron center. X-ray crystallography revealed that the dimer has a short Fe–Ni separation of 2.797(1) Å and Fe–N–O angles of 167.0(5) and 174.6(5)°. The infrared spectrum exhibits two intense bands attributed to the symmetric and asymmetric stretching modes of the nitrosyl ligands at 1663 and 1624 cm^{-1} .

A binuclear nickel-iron complex is formed by the reaction of $[\text{Fe}(\text{CO})\text{N}(\text{CH}_2\text{CH}_2\text{S})_3]^-$ with $\text{NiCl}_2(\text{dppe})$ under an atmosphere of carbon monoxide [84]. One of the chloride ligands is displaced from nickel and two of the thiolato donors adopt bridging modes while the iron becomes six-coordinate by addition of one CO ligand. The dimer is characterized by a long Fe–Ni separation of 3.308 Å, much longer than that found reported for the hydrogenase enzyme of *D. gigas* [60]. The IR spectrum exhibits intense absorptions at 1944 and 2000 cm^{-1} which is assigned to the axial and equatorial CO ligands, respectively.

Two recent reports present the displacement of carbon monoxide ligands by addition of cyanide to iron carbonyl dimers. In the first report [85] the addition of cyanide to the known complexes $[\text{Fe}(\text{CO})_3]_2(\mu\text{-SMe})_2$ (see Ref. [86].) or $[\text{Fe}(\text{CO})_3]_2(\mu^2\text{-SCH}_2\text{CH}_2\text{CH}_2\text{S})$ (see Ref. [87].) results in the formation of $[\text{Fe}(\text{CN})(\text{CO})_2]_2(\mu\text{-SMe})_2^{2-}$ or $[\text{Fe}(\text{CN})(\text{CO})_2]_2(\mu^2\text{-SCH}_2\text{CH}_2\text{CH}_2\text{S})^{2-}$, respectively. The synthesis and structure of the latter complex is also the subject of the second report [88]. Attempts to prepare a monocyano-substituted complex were unsuccessful and the use of excess cyanide lead to the formation of the same dicyano complex. X-ray crystallographic studies of $(\text{Ph}_4\text{P})_2[\text{Fe}(\text{CN})(\text{CO})_2]_2(\mu\text{-SMe})_2$ were foiled by the co-crystallization of isomers where the methyl thiolate ligands are disposed to create a mixture of diequatorial and equatorial, axial isomers. These isomers are in equilibrium and the latter isomer is favored four to one. X-ray crystallographic studies of $(\text{Et}_4\text{N})_2[\text{Fe}(\text{CN})(\text{CO})_2]_2(\mu^2\text{-SCH}_2\text{CH}_2\text{CH}_2\text{S})$ reveal a short Fe–Fe separation 2.517 Å. This distance is within bonding range and shorter than the 2.6 Å separation observed in the two protein structures.

7.3.5 Theoretical Modeling

The crystallographic studies have provided the theoretical studies with the fodder to make models to better understand the chemistry of the active sites of $[\text{FeNi}]$ - and $[\text{Fe}]$ -hydrogenases. The theoretical models start with the coordinates from the X-ray crystal structures and use density functional theory (DFT) to handle the complexity of these transition-metal systems. The geometries are optimized and the energies calculated using some level of theory. The catalytic cycle is then explored by preparing a number of models using assumptions about what species are involved in the catalytic cycle. In the presentation of the theoretical models that follows we will present the assumptions of each model system and the implications about the chemistry of the active site that are gleaned.

In one model system, that uses DFT and the B3LYP level of theory, the dinuclear cluster is assumed to be neutral in all states [89]. The active site coordinates are taken from the crystal structure of the $[\text{FeNi}]$ -hydrogenase from *D. gigas* [60] and two cyanide ligands and one carbonyl ligand are added. The cysteine residues are modeled as either HS^- or H_2S . The bridging ligands are modeled as HS^- since H_2S results in dissociation of these ligands. This model has reasonable metal thiolate distances (2.8–3.0 Å) and a bent structure with a Fe–S–Ni angle close to 90°. The terminal cysteine residues are modeled in the same manner: as two thiolates, two thiols, or one of each. Taken together with the assumption of cluster neutrality,

each of these states requires a different set of oxidation states for the two metals. The model with two terminal HS ligands uses Ni(III) and Fe(III) oxidation states to maintain overall neutrality. This model is ruled out as the reaction with H₂ is calculated to be far too exothermic. The other two models more faithfully reproduce the experimental results. The model with two terminal H₂S ligands requires Ni(II)–Fe(II) oxidation states for the cluster while the mixed H₂S/HS-model needs Ni(III)–Fe(II) or Ni(II)–Fe(III) oxidation states. Of these two models, the mixed ligand system reproduces the experimental energetics. In this model only the iron is found as a site for H₂ binding. The catalytic cycle suggested by these calculations involves transfer of a proton from the iron-bound dihydrogen to a bridging HS-ligand. This newly formed H₂S bridge dissociates from the nickel center and one of the cyanide ligands forms a Fe–CN–Ni bridge. A mechanism where this proton is transferred to a protein residue cannot be ruled out. Throughout this mechanism of H₂ oxidation the formal oxidation states of the metals do not change. This apparent contradiction is due to the formal assignment of hydride ligands as H whereas thiol hydrogens are treated as H⁺. Thus the two electrons from H₂ oxidation are allotted to the hydride ligand without changing the oxidation state of the metals. One of the merits of this model is the low energy barrier for the H₂ activation step that is in good agreement with the experimental value. The catalytic cycle proceeds with a hydride transfer from iron to nickel.

A second model of [FeNi]-hydrogenase, that also uses DFT with the B3LYP level of theory, uses the infrared spectroscopy results as a check of the quality of the model in a given state [90]. This test makes use of the observation that the C–O stretching frequencies correlate well with the C–O bond length [91]. Since the C–O stretching frequency is sensitive to changes in the electron density of the iron center, it reflects the electronic distribution. In this manner the ability of the model to reproduce the electronic state is assessed. In this model system the cysteine residues are modeled as methyl thiolate ligands and the charge on the metal cluster is not restricted to neutrality. One of the main features of this model is the ability of the thiolate bridges to fold when one of the terminal thiolates is protonated. The mechanism starts with one of these bent structures. The **SI** state exists as a mixture of protonation states which in this model are [(MeS)₂Ni(μ-MeS)₂Fe(CN)₂(CO)]²⁻ and [(MeS)(MeSH)Ni(μ-MeS)₂Fe(CN)₂(CO)]⁻. The latter complex reacts with H₂ and again the iron is found to be the site of H₂ activation. The mechanism proceeds by oxidation of the nickel(II) ion. The dihydrogen unit is split heterolytically to form (MeSH)₂Ni(μ-H)(μ-MeS)₂Fe(CN)₂(CO). This cluster loses a proton from a terminal methane thiol ligand followed by a rearrangement where the hydride ligand is transferred as a proton to regenerate the methane thiol ligand and form nickel(I). The oxidation of the nickel(I) center and loss of a proton from one of the methane thiol ligands recreates the initial species of the catalytic cycle.

In a third theoretical model the [FeNi]-hydrogenase from *D. gigas* is modeled using a hybrid density functional theory–molecular mechanics (DFT/MM) method [92]. In this model approximately 30 atoms of the active site (including the four cysteine residues) are modeled with DFT while molecular mechanics is used for the rest of the atoms within a 7 Å radius (about 300 atoms). The next shell includes about 10 000 protein and solvent atoms within 27 Å of the active site whose posi-

tions are not optimized. A 45 Å radius shell of water molecules rounds out the model. The inclusion of the protein and water matrix provides an improvement over the previous models that use a vacuum medium. This is reflected by the observation that the calculated C–O stretching frequencies are consistently lower when the protein and solvent matrix are excluded. The active states of the enzyme are modeled with a bridging hydride ligand replacing the bridging oxide of the inactive form. Thus the model of the active site in the **SI** state can be represented as $[(\text{Cys})_2\text{Ni}(\mu\text{-H})(\mu\text{-Cys})_2\text{Fe}(\text{CN})_2(\text{CO})]^{3-}$. Unlike the previous two models, nickel is invoked as the site of dihydrogen attack in this model, though an exhaustive search for alternative binding sites was not performed. The attack of dihydrogen on the nickel ion results in heterolytic activation with the formation of a nickel hydride and a protonated cysteine residue.

A DFT model of the [Fe]-hydrogenase from *C. pasteurianum* has also appeared [93]. This model uses $[(\text{MeS})(\text{CO})(\text{CN})\text{Fe}(\mu\text{-S})_2(\mu\text{-CO})\text{Fe}(\text{CO})(\text{CN})]^{z-}$, where z is the overall charge on the cluster. One of the unique features of this model is that the two bridging sulfides are redox active, being represented as either two sulfide, S^{2-} , ions or as one persulfide, S_2^{2-} , ion, a difference of two electrons. A similar property has not been proposed for the bridging cysteines in the [FeNi]-hydrogenase models. The bridging carbonyl ligand is found to have a low energy barrier to shifting to coordination to the distal iron. This distal iron atom is also a site of dihydrogen coordination, though the binding is weak. There is a low energy path to transfer of a proton to one of the bridging sulfides.

7.4 Conclusions

Much information on the nature of the active sites of hydrogenase enzymes has been gleaned from studies on the enzymes as well as from studies of model systems. The information we have presented here demonstrates how each of these areas of study has contributed towards illuminating the chemistry of the hydrogenase enzymes. While the enzyme studies reveal much about the possible mechanisms by which hydrogenase enzymes might operate, it is the modeling studies that will provide the information required for a full understanding of these complex enzymatic systems. Modeling studies reveal much of the hidden workings of the enzymes. The techniques are complementary. Studies of the hydrogenase enzymes provide the scaffold around which modeling studies can build a viable mechanism of dihydrogen activation or production.

A number of generalities can be drawn from the similarities that are observed between the three classes of enzymes, [Fe]-, [FeNi]-, and [FeNiSe]-hydrogenases. The similarities in the structure of the active sites are the most pertinent for the purposes of modeling experiments. The three classes of enzymes share a common iron center with two cyanide ligands and one carbon monoxide ligand. This moiety was first proposed from experiments on the enzyme and confirmed by model studies. This $[\text{Fe}(\text{CN})_2(\text{CO})]$ moiety is connected to a second metal ion which is either

nickel or iron, depending on the class of hydrogenase enzyme. This second metal is potentially redox active and is bridged to the dicyano carbonyl iron center via two cysteine residues. This second metal center has two terminal ligands that are either cysteine or selenocysteine. These similarities suggest a common mechanism of H_2 activation for all three classes of hydrogenase enzyme. Given that no model nickel compound has been reported to activate dihydrogen we are left to conclude that it is the $Fe(CN)_2(CO)$ unit which is responsible for H_2 -activation. The Ni-61 EPR studies would then suggest that the second metal site could act as a hydride reservoir. For now this is merely speculation though it does account for some of the interesting properties of the enzymes.

In addition to the common features of the three classes of hydrogenase it is instructive to examine the differences that exist between them. One of the most obvious differences is the function of the different classes of hydrogenase. The [Fe]-hydrogenase enzymes are primarily H_2 -activating while the [FeNi]- and [FeNiSe]-hydrogenase enzymes are H_2 -producing. This is an over-simplification as there are hydrogenase enzymes that are able both to form H_2 as well as to activate H_2 . It does, however, suggest that the enzymes have evolved with a preference for the metal which better enables it to perform the task of either activating or producing dihydrogen.

8 Biomimetic Electron-transfer Chemistry of Porphyrins and Metalloporphyrins

Shunichi Fukuzumi and Hiroshi Imahori

8.1 Introduction

Porphyrins contain an extensively conjugated π system and a highly delocalized π system such as this is suitable for efficient electron-transfer reactions, because the uptake or release of electrons results in minimal changes of structure and solvation on electron transfer [1]. Numerous metal ions can tightly bind with porphyrin macrocyclic ligands to afford metalloporphyrins which can undergo metal-centered electron-transfer reactions and porphyrin ligand-centered reactions [1]. Therefore, a variety of redox states can be achieved for metalloporphyrins through multi-electron oxidation or reduction processes [1]. Metalloporphyrins can form a metal-carbon σ -bond to afford organometallic porphyrins [2]. The strength of such binding is significantly altered, depending on the redox state of metalloporphyrins [2]. Consequently, cleavage or formation of the metal-carbon bond can be finely tuned by changing the redox state. Thus, the electron transfer oxidation or reduction of metalloporphyrins and organometallic porphyrins is often accompanied by the subsequent formation or cleavage of the bond, leading to a rich chemistry for metalloporphyrins and organometallic porphyrins [1, 2]. Such formation of reactive intermediates associated with electron-transfer reactions of metalloporphyrins has played an important role in the catalytic function of metalloporphyrins not only in chemical but also in biological processes [3–5]. Axial ligands can also bind or coordinate to the metal to attenuate the electron-transfer reactions of metalloporphyrins including the site of electron transfer, i.e. metal-centered or the porphyrin ligand-centered electron transfer [1]. The use of photoexcited states of porphyrins and metalloporphyrins (i.e., in the singlet or triplet excited state) further widens the scope of electron-transfer reactions, because photoexcitation significantly enhances both the electron-acceptor or -donor properties of photoexcited porphyrins and metalloporphyrins. The rich redox properties of porphyrins and metalloporphyrins both in the ground and excited states have rendered them es-

sential components of biological electron transport systems including photosynthesis and respiration [6–15].

Because the electron-transfer processes of porphyrins and metalloporphyrins have been reviewed elsewhere [1, 16, 17], this chapter focuses on mechanistic aspects of chemical processes associated with the electron-transfer reactions of metalloporphyrins and organometallic porphyrins. When an electron-transfer process is followed by subsequent bond-breaking and bond-forming, the overall reaction often becomes the same as electrophile–nucleophile reactions in which electron shift and bond formation occur in a concerted manner via a polar mechanism. Such electron transfer or alternative polar (concerted) processes have been among the most central propositions in reaction mechanisms [18–26]. Because both processes involve the formation of a significant amount of charge in the transition state, it has been difficult to differentiate between electron transfer and polar mechanisms on the basis of the classical approach of electronic and substitution effects. Advances in time-resolved spectroscopy, including laser flash photolysis and a low-temperature stopped-flow technique, have, however, provided the means of monitoring fast electron-transfer reactions and subsequent chemical reactions, by enabling detection of unstable reactive intermediates produced in electron-transfer reactions.

In the first part of this review, recent advances in the mechanistic aspects of reactions of high-valent metalloporphyrin intermediates produced by the oxidation of metalloporphyrins and organometallic porphyrins are highlighted in relation to the enzymatic reaction mechanisms of biological oxidation of substrates including water. This section is followed by an overview of the reverse process, i.e. the four-electron reduction of O₂ to water catalyzed by cytochrome c oxidases and model complexes. Finally biomimetic electron-transfer systems of porphyrins and metalloporphyrins in organized media are presented in relation to practical endeavors such as the design of molecular-scale photonic devices and solar-energy conversion systems.

8.2 High-valent Intermediates of Heme Enzymes

8.2.1 P-450 Catalytic Mechanisms

Cytochromes P-450, the CO complexes of which have a characteristic absorption maximum at 450 nm, use molecular oxygen to catalyze monooxygenation of versatile organic compounds such as hydrocarbons, sulfides, and amines with reducing agents (Eq. 1) [27–33].

For decades extensive efforts have been devoted to the elucidation of the molecular mechanisms of oxygen activation and oxidation reactions. The following mechanism is generally assumed for dioxygen activation and monooxygenation (Scheme 1) [27–33].

Scheme 1.

Starting from the low-spin Fe^{III} state of a six-coordinate metalloporphyrin complex with cysteinate and water, the binding of an organic substrate (RH) occurs to give the high-spin Fe^{III} state. This step is followed by a one-electron reduction via 5,10-dihydroflavin adenine dinucleotide (FADH₂) to give a high-spin Fe^{II} complex which can bind oxygen. After a second one-electron reduction to a high-spin Fe^{II} complex, a low-spin peroxo Fe^{III} complex is formed. Two protons are then added to produce a high-valent iron-oxo porphyrin π radical cation, [(P)Fe^{IV}=O]^{•+} (or a formally pentavalent iron-oxo complex [(P)Fe^V=O]) by release of one water molecule, thereby cleaving the O–O bond. Formal oxygen transfer from [(P)Fe^{IV}=O]^{•+} to RH occurs to yield the monooxygenated product, accompanied by regeneration of the starting low-spin Fe^{III} state (Scheme 1). The high-valent iron-oxo porphyrin

$[(P)Fe^{IV}=O]^{*+}$ or $(P)Fe^V=O$) is the reactive intermediate in the monooxygenation step.

The use of a synthetic model system has provided valuable mechanistic insights into the molecular catalytic mechanism of P-450. Groves et al. [34], were the first to report cytochrome P-450-type activity in a model system comprising iron *meso*-tetraphenylporphyrin chloride $[(TPP)FeCl]$ and iodosylbenzene (PhIO) as an oxidant which can oxidize the Fe^{III} porphyrin directly to $[(TPP)Fe^{IV}=O]^{*+}$ in a 'shunt' pathway. Thus, $(TPP)FeCl$ and other metalloporphyrins can catalyze the monooxygenation of a variety of substrates by PhIO [35–40], hypochlorite salts [41, 42], *p*-cyano-*N,N*-dimethylaniline *N*-oxide [43–46], percarboxylic acids [47–50] and hydroperoxides [51, 52]. Catalytic activity was, however, rapidly reduced because of the destruction of the metalloporphyrin during the catalytic cycle [34–52]. When $(TPP)FeCl$ was immobilized on the surface of silica or silica–alumina, catalytic reactivity and catalytic lifetime both increased significantly [53]. There have been several reports of supported catalysts based on such metalloporphyrins adsorbed or covalently bound to polymers [54–56]. Catalyst lifetime was also significantly improved by use of iron porphyrins such as *meso*-tetramesitylporphyrin chloride $[(TMP)FeCl]$ and iron *meso*-tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrin chloride $[(TPFPP)FeCl]$, which resist oxidative destruction, because of steric and electronic effects and thereby act as efficient catalysts of P-450 type reactions [57–65].

8.2.2 Reaction Pathways of $[(P)Fe^{IV}=O]^{*+}$

In the catalytic cycle in Scheme 1, details of the reaction between the high-valent iron–oxo porphyrin π radical cation $[(P)Fe^{IV}=O]^{*+}$ and a substrate have yet to be clarified [66]. Three possibilities have survived after extensive studies of the mechanisms of the reactions of high-valent iron–oxo porphyrins, in particular the dealkylation of amines by cytochrome P-450: (A) a sequential electron–proton–electron transfer; (B) direct hydrogen transfer then electron transfer; and (C) electron transfer followed by hydrogen transfer (Scheme 2) [67–74].

It was believed that a sequential electron–proton–electron transfer mechanism would result in small isotope effects and that a hydrogen transfer mechanism would result in large isotope effects. Because small isotope effects were observed for amine dealkylation by cytochrome P-450, a sequential electron–proton–electron transfer mechanism was proposed for the reaction [67, 75–77]. The magnitude of a single isotope effect provides only limited information about a reaction mechanism, however, and isotope effects might be logically consistent with any type of C–H cleavage reaction.

To distinguish between paths A and B in Scheme 2, Dinnocenzo and coworkers [78–80] determined intramolecular isotope effects for deprotonation from the radical cations (path A) and for hydrogen-atom abstraction from a series of substituted *N,N*-dimethylanilines (path B); these were compared with isotope effects for *N*-demethylation of the same series of *N,N*-dimethylanilines. The deprotonation isotope-effect profile for the radical cations of *N,N*-dimethylanilines were determined by monitoring electron-transfer reactions from *N,N*-dimethylanilines to $[Fe(phen)_3]^{3+}$

Scheme 2.

(phen = 1,10-phenanthroline), a well-known outer-sphere one-electron oxidant [81], in the presence of pyridine as base. The mechanism of such electron-transfer reactions has been well established in electron-transfer reactions of NADH analogs with $[\text{Fe}(\text{phen})_3]^{3+}$ in the presence of pyridine [82–84], and can be applied to the reaction of *N,N*-dimethylanilines as shown in Scheme 3.

The rate of initial electron transfer from *N,N*-dimethylaniline to $[\text{Fe}(\text{phen})_3]^{3+}$ is diffusion-limited. This is followed by the rate-determining proton transfer from the radical cation to pyridine to give the deprotonated α -amino radical which is rapidly oxidized by a second equivalent of $[\text{Fe}(\text{phen})_3]^{3+}$ to yield the product iminium ion. Kinetic isotope effects ($k_{\text{H}}/k_{\text{D}}$) for the proton transfer were determined from the d_3/d_0 ratios of the products derived from *p*-substituted *N*-methyl-*N*-trideuteromethylanilines. The $k_{\text{H}}/k_{\text{D}}$ value first increases and then decreases with increasing $\text{p}K_{\text{a}}$ of *p*-substituted *N,N*-dimethylaniline. Such a bell-shaped isotope effect profile is typical of proton-transfer reactions [82, 85]. The maximum $k_{\text{H}}/k_{\text{D}}$ value is determined as 8.8 which is much larger than the corresponding value for the demethylation of the same substrate by cytochrome P-450 (2.6) [79].

The isotope effect profile for hydrogen atom abstraction from the same series of *p*-substituted *N,N*-dimethylanilines was determined by using the *tert*-butoxyl radical (*t*-BuO $^\bullet$) as the hydrogen-atom abstracting agent; this species is known to abstract hydrogen atoms from the α -carbon atoms of amines [86]. The *tert*-butoxyl radical was generated by the coumarin-sensitized photoreduction of the *N-tert*-butoxy-4-phenylpyridinium ion [87, 88]. A small, steady decrease in the $k_{\text{H}}/k_{\text{D}}$ value for hydrogen-atom abstraction from *p*-substituted *N,N*-dimethylanilines is observed when the $\text{p}K_{\text{a}}$ of the radical cations is increased. This is quite different from the bell-shaped isotope-effect profile for the proton-transfer reactions. Such differences demonstrate that isotope profiles can serve as sensitive probes for distinguishing

Scheme 3

P-450 amine dealkylation mechanisms. Because $k_{\text{H}}/k_{\text{D}}$ values for *N*-demethylation of *p*-substituted *N,N*-dimethylanilines by cytochrome P-450 are nearly identical with those for the hydrogen abstraction reactions of *t*-BuO \cdot , it was proposed that P-450 reacted by a direct hydrogen-atom-abstraction mechanism (**B**) rather than a sequential electron-proton-electron-transfer mechanism (**A**) [78, 80]. Identical relationships between $k_{\text{H}}/k_{\text{D}}$ values for reactions of *t*-BuO \cdot and P-450 has been expanded for other substrates including *p*-xylene, toluene, benzyl alcohol, and tertiary trialkylamine [78]. It has thus been suggested that all these P-450 reactions proceed by a common hydrogen-atom transfer mechanism [78].

For a synthetic P-450 model system, however, an opposite conclusion was drawn from similar analysis of kinetic isotope effects for *N*-demethylation of *p*-substituted *N,N*-dimethylanilines by PhIO, catalyzed by iron *meso*-tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrin chloride, (TPFPP)FeCl [89]. Intramolecular $k_{\text{H}}/k_{\text{D}}$ values obtained from the d_3/d_0 ratios of the products derived from 4-*X-N*-methyl-*N*-tri-deuteriomethylanilines [2.0 ($\text{X} = \text{NO}_2$), 2.0 ($\text{X} = \text{CN}$), 2.6 ($\text{X} = \text{Br}$), 3.1 ($\text{X} = \text{H}$), 3.2 ($\text{X} = \text{Me}$), and 3.3 ($\text{X} = \text{OMe}$)], decreased regularly on going from electron-donating to electron-withdrawing substituents. Such a trend is the complete oppo-

site to that found for the hydrogen-atom-abstraction reactions of some of these substrates with *t*-BuO[•], but also different from the bell-shaped isotope-effect profile obtained for proton-transfer reactions (vide supra) [89]. The intermolecular $k_{\text{H}}/k_{\text{D}}$ values were also determined by competitive experiments with 4-X-substituted *N,N*-dimethyl- and *N,N*-bis(trideuteromethyl)anilines, with X = H, Br, and OMe, as 1.6, 1.5 and 1.9, respectively. These values are quite different from the corresponding intramolecular $k_{\text{H}}/k_{\text{D}}$ values. Such a difference between intramolecular and intermolecular kinetic isotope effects implies a multi-step rather than single-step reaction. An electron transfer pathway followed by hydrogen transfer (C in Scheme 2) is consistent with these results.

8.2.3 Reorganization Energies for Electron-transfer Reactions of High-valent Iron Porphyrins

The electron transfer pathway has been examined by analyzing relative reactivities of 4-X-substituted *N,N*-dimethylanilines, determined by competitive kinetics; the reactivities span a wide reactivity range of 25 (from X = NO₂ to X = MeO) and can be fitted to the Rehm–Welter equation [90] for electron-transfer reactions (Eq. 2):

$$\Delta G^\ddagger = (\Delta G^\circ_{\text{et}}/2) + [(\Delta G^\circ_{\text{et}}/2)^2 + (\Delta G^\ddagger_0)^2]^{1/2} \quad (2)$$

where $\Delta G^\circ_{\text{et}}$ is the free energy change for electron transfer and ΔG^\ddagger_0 is the intrinsic barrier that represents the activation free energy when the driving force of electron transfer is zero, i.e., $\Delta G^\ddagger = \Delta G^\ddagger_0$ at $\Delta G^\circ_{\text{et}} = 0$ [90]. The ΔG^\ddagger values are related to the rate constant of electron transfer (k_{et}) as given by Eq. 3, where Z is the collision frequency (i.e., $1 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$).

$$\Delta G^\ddagger = 2.3RT \log(Z/k_{\text{et}}) \quad (3)$$

The k_{et} values can be calculated from the $\Delta G^\circ_{\text{et}}$ and ΔG^\ddagger_0 values by use of Eqs 2 and 3. The $\Delta G^\circ_{\text{et}}$ value is obtained from the one-electron oxidation potential of an electron donor (E°_{ox}) and the one-electron reduction potential of an acceptor (E°_{red}), because $\Delta G^\circ_{\text{et}} = F(E^\circ_{\text{ox}} - E^\circ_{\text{red}})$.

The reorganization energy of electron transfer (λ) is defined as $4\Delta G^\ddagger_0$. The λ value was evaluated as 47 kcal mol^{−1} for the postulated electron transfer from *N,N*-dimethylanilines to [(TPFPP)Fe^{IV}=O]^{•+} by fitting the data to Eqs 2 and 3. Essentially the same λ value can be obtained by fitting the data to the Marcus equation (Eq. 4) [91] except for the region where the rate becomes close to a diffusion-limited value [81, 92].

$$\Delta G^\ddagger = (\lambda/4)[1 + (\Delta G^\circ_{\text{et}}/\lambda)]^2 \quad (4)$$

Although such a large λ value is rather unusual in electron-transfer reactions of metalloporphyrins [1], the electron transfer kinetics for generation of iron(IV) por-

Scheme 4.

phyrins or iron(IV) porphyrin π radical cations indicated a large reorganization energy was required for electron-transfer reactions involving high-valent metalloporphyrins [93]. The investigated compounds are represented as (P)Fe(R) where P^{2-} = the dianion of 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetraphenylporphyrin (OETPP) and $\text{R} = \text{C}_6\text{H}_5$, 3,5- $\text{C}_6\text{F}_2\text{H}_3$, 2,4,6- $\text{C}_6\text{F}_3\text{H}_2$, or C_6F_5 , or P^{2-} = the dianion of 2,3,7,8,12,13,17,18-octaethylporphyrin (OEP) and $\text{R} = \text{C}_6\text{H}_5$, 2,4,6- $\text{C}_6\text{F}_3\text{H}_2$, or 2,3,5,6- $\text{C}_6\text{F}_4\text{H}$.

The first one-electron transfer from (P)Fe(R) to $[\text{Ru}(\text{bpy})_3]^{3+}$ (bpy = 2,2'-bipyridine) leads to an Fe(IV) σ -bonded complex, $[(\text{P)Fe}^{\text{IV}}(\text{R})]^+$ [94], and occurs at a rate which is much lower than that of the second one-electron transfer from $[(\text{P)Fe}^{\text{IV}}(\text{R})]^+$ to $[\text{Ru}(\text{bpy})_3]^{3+}$ to give $[(\text{P)Fe}^{\text{IV}}(\text{R})]^{2+}$ (Scheme 4).

Metal-centered oxidation is therefore kinetically more difficult than the porphyrin macrocycle oxidation. The reorganization energies (λ in kcal mol^{-1}) for the metal-centered oxidation of (OETPP)Fe^{III}(R) to [(OETPP)Fe^{IV}(R)]⁺ ($\text{R} = \text{C}_6\text{H}_5$, 3,5- $\text{C}_6\text{F}_2\text{H}_3$, and 2,4,6- $\text{C}_6\text{F}_3\text{H}_2$), (OETPP)Fe^{III}(C_6F_5) to [(OETPP)Fe^{IV}(C_6F_5)]⁺, and (OEP)Fe^{III}(R) to [(OEP)Fe^{IV}(R)]⁺ are 54, 49, and 42 kcal mol^{-1} , respectively [93]. Each is significantly larger than reorganization energies for the porphyrin-centered oxidations involving the same series of compounds, i.e. the second electron transfer of (P)Fe(R) for the ligand-centered oxidation, ca 24 kcal mol^{-1} , which is comparable with the λ value for free base porphyrins [95]. Thus, a large reorganization energy is required for the electron-transfer oxidation of (P)Fe^{III}(R) to [(P)Fe^{IV}(R)]⁺. It is interesting to note that the λ value (49 kcal mol^{-1}) for the electron transfer oxidation of (OETPP)Fe^{III}(C_6F_5) to [(OETPP)Fe^{IV}(C_6F_5)]⁺ is approximately the same as the λ value (47 kcal mol^{-1}) for the postulated electron-transfer reduction of $[(\text{TPFPP)Fe}^{\text{IV}}=\text{O}]^{+}$ by *N,N*-dimethylanilines (vide infra) [89].

8.2.4 Electron-transfer Pathway of $[(\text{P)Fe}^{\text{IV}}=\text{O}]^{+}$

To clarify the mechanism of reaction of P-450, it is crucial to characterize the reactive intermediates in the rate-determining step. Definitive evidence for an electron-transfer mechanism (C in Scheme 2) for the *N*-demethylation of *N,N*-dimethylanilines has been obtained by direct observation of the reduction of the high-valent species responsible for P-450 catalysis [96]. For peroxidase, an oxoferryl porphyrin π -radical cation, compound I $[(\text{P)Fe}^{\text{IV}}=\text{O}]^{+}$, has been well characterized as the species equivalent to the proposed active intermediate of P-450 [97–103]. Compound I of horseradish peroxidase (HRP) can be readily generated by chemical oxidation of HRP [100–103]. The involvement of the electron-transfer process of compound I in the oxidation of several amines catalyzed by HRP was

Figure 1. Dependence of kinetic values on the oxidation potential of DMA (E°_{ox}). (a) (\diamond): bimolecular rate constant of HRP compound **I** with DMA, k_1 . (b) (\circ): bimolecular rate constant of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ with DMA, k_3 . (c) (Δ): $k_{\text{et}}/k_{\text{H}}$ determined by use of Eq. 6 [96].

demonstrated by the ESR detection of the corresponding aminium radicals [97–99]. Reactions of compound **I** with 4-X-substituted *N,N*-dimethyl- and *N,N*-bis(trideuteriomethyl)anilines (DMA) were monitored spectroscopically by use of a double-mixing stopped-flow technique [96]. When HRP compound **I** and the amines were mixed under stopped-flow conditions in a buffer solution (pH 7.0) at 273 K, rapid formation of compound **II** $[(\text{P})\text{Fe}^{\text{IV}}=\text{O}]$ (k_1) and the subsequent relatively slow conversion (k_2) to the resting ferric state were observed directly. Both $\log k_1$ and $\log k_2$ increase with decreasing E°_{ox} as the electron-transfer process becomes thermodynamically more favorable. A linear correlation between $\log k_1$ and E°_{ox} is shown in Figure 1a. No kinetic isotope effects are observed. Thus, the rate-determining step is clearly electron transfer from DMA to HRP compound **I** and compound **II**.

According the Marcus theory of outer-sphere electron-transfer (Eq. 4), the slope of a linear correlation between $\log k_1$ and E°_{ox} can be derived as given by Eq. 5.

$$\partial(\log k_1)/\partial(E^\circ_{\text{ox}}) = -\frac{1}{2}(1/2.3RT)(1 + \Delta G^\circ_{\text{et}}/\lambda) \quad (5)$$

The slope of the linear correlation between $\log k_1$ and E°_{ox} (-7.65) is slightly less negative than the value (-9.2) expected from Eq. 5 at $\Delta G^\circ_{\text{et}} = 0$

$[\partial(\log k_1)/\partial(E^\circ_{\text{ox}})] = -(1/2)(1/2.3RT) = -9.2$ at 273 K]. This means that electron transfer from DMA to HRP compound **I** is slightly exergonic, because $\partial(\log k_1)/\partial(E^\circ_{\text{ox}}) > -(1/2)(1/2.3RT) = -9.2$ at 273 K when $\Delta G^\circ_{\text{et}} < 0$. This is consistent with the highly positive one-electron reduction potential of HRP compound **I** ($E^\circ_{\text{red}} = 0.898$ V relative to the NHE, or 0.662 V relative to the SCE) [104]. The unknown value of the reorganization energy (λ) for electron-transfer reactions from *N,N*-dimethylanilines to HRP compound **I** and the experimental errors involved in estimating the redox potentials in water have precluded complete fit of the rate constants to values calculated from Eqs 3 and 4, although a linear correlation between $\log k_1$ and E°_{ox} for a wide range of E°_{ox} indicates that a large reorganization energy is required for the electron-transfer reduction of compound **I**, i.e. $|\Delta G^\circ_{\text{et}}/\lambda| \ll 1$ in Eq. 5 as postulated for electron transfer from *N,N*-dimethylanilines to $[(\text{TPFPP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ (vide supra) [89]. A large reorganization energy ($\lambda = 61.9$ kcal mol⁻¹) [104] has, in fact, been derived from the electron self-exchange rate between HRP compound **I** and compound **II** (4.4×10^{-1} M⁻¹ s⁻¹) by applying the Marcus theory of electron transfer (Eq. 4) [91] to the rate of electron transfer from ferrocyanide to HRP compound **I** (8×10^5 M⁻¹ s⁻¹) [105]. An even larger reorganization energy ($\lambda = 78.0$ kcal mol⁻¹) [104] was derived from the electron self-exchange rate between HRP compound **II** and ferric HRP (4.9×10^{-4} M⁻¹ s⁻¹) [104]. The extremely large λ value (78.0 kcal mol⁻¹) for the metal-centered electron-exchange between HRP compound **II** (Fe^{IV}) and ferric HRP (Fe^{III}) is consistent with the large λ value (83 kcal mol⁻¹) derived from the reaction between $[(\text{OEP})\text{Fe}^{\text{IV}}(\text{R})]^{*+}$ and $(\text{OEP})\text{Fe}^{\text{III}}(\text{R})$ [93]. The large λ value for electron self-exchange between HRP compound **I** and compound **II** ($\lambda = 78.0$ kcal mol⁻¹) [104] suggests a significant contribution of the metal-centered reduction of $[(\text{P})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ to give compound **II**, which should have $(\text{P})\text{Fe}^{\text{III}}-\text{O}^\bullet$ character as another resonance form of $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$. This system can be used as an authentic case for the electron-transfer reactivity of compound **I** with *N,N*-dimethylanilines which can be compared with the reactivities of compound **I** of P-450 and of synthetic analogs with the same substrates.

Although characterization of compound **I** of P-450 has remained poor [106], compound **I** of a synthetic model, i.e., $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ has been well characterized spectrophotometrically [107]. $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ was prepared by reaction of $(\text{TMP})\text{Fe}^{\text{III}}(\text{OH})$ with *m*-chloroperoxybenzoic acid (*m*CPBA) in CH₂Cl₂ at 223 K [193]. The reactions of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ with 4-X-substituted *N,N*-dimethylanilines (DMA) in CH₂Cl₂ at 223 K were monitored by UV-Vis spectral changes of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ and found to afford $(\text{TMP})\text{Fe}^{\text{III}}$ without observation of any intermediates [96]. There is linear correlation between the rate constants (k_3) and E°_{ox} (Figure 1b), similar to the correlation observed for $\log k_1$ and E°_{ox} (Figure 1a). The parallel relationship between these two plots indicates that electron transfer from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ plays an important role in the rate-determining step for the reaction of the P-450 model complex with DMA. Kinetic isotope effects are, however, clearly observed for reactions of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ with 4-X-substituted *N,N*-dimethyl- and *N,N*-bis(trideuteromethyl)anilines. The $k_{3\text{H}}/k_{3\text{D}}$ value increases with increasing E°_{ox} from a value close to unity (1.3 for X = OMe) to a large value of 5.9 for X = NO₂ [96]. More importantly, there is a large difference between the intermolecular kinetic isotope effects ($k_{3\text{H}}/k_{3\text{D}}$) and intramolecular isotope effects

Scheme 5.

$(k_{\text{H}}/k_{\text{D}})$ derived from product analysis (e.g., $k_{3\text{H}}/k_{3\text{D}} = 1.3$, $k_{\text{H}}/k_{\text{D}} = 3.9$ for $\text{X} = \text{OMe}$) [96]. The small $k_{\text{H}}/k_{\text{D}}$ values compared with those for proton-transfer reactions of $\text{DMA}^{\cdot+}$ [79] indicate that a proton-transfer step is unlikely to be involved. Thus, the rate-determining step might involve a hydrogen atom-transfer step after the initial electron transfer, as shown in Scheme 5 (mechanism C in Scheme 2).

If this is so, the product isotope effect reflects the hydrogen-transfer step (k_{H}) from the radical cation of *N,N*-dimethylaniline ($\text{DMA}^{\cdot+}$) to $(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}$ in competition with the back-electron-transfer step ($k_{\text{-et}}$). With decreasing one-electron oxidation potential (E°_{ox}) of DMA, equivalent to the one-electron reduction potential (E°_{red}) of $\text{DMA}^{\cdot+}$, the rate of back-electron-transfer from $(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}$ to $\text{DMA}^{\cdot+}$ decreases, becoming slower than the hydrogen-transfer step, at which point the electron-transfer step from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\cdot+}$ becomes the rate-determining step. This might be the reason why the kinetic isotope effect is close to unity for $\text{X} = \text{OMe}$ ($k_{3\text{H}}/k_{3\text{D}} = 1.3$) whereas the product isotope effect directly reflects the hydrogen-transfer step ($k_{\text{H}}/k_{\text{D}} = 3.9$ for $\text{X} = \text{OMe}$). For $\text{X} = \text{NO}_2$ the hydrogen-transfer step might be the rate-determining step, because of the fast back-electron-transfer whereby the $k_{3\text{H}}/k_{3\text{D}}$ value (5.9) becomes nearly the same as the $k_{\text{H}}/k_{\text{D}}$ value (6.2). According to Scheme 5, a quantitative relationship can be derived between the kinetic isotope effects ($k_{3\text{H}}/k_{3\text{D}}$) and the product isotope effects ($k_{\text{H}}/k_{\text{D}}$); this is given by Eq. 6 [96].

$$k_{3\text{H}}/k_{3\text{D}} = (k_{\text{H}}/k_{\text{D}}) \{ (k_{\text{D}}/k_{\text{H}}) + (k_{\text{-et}}/k_{\text{H}}) \} / \{ 1 + (k_{\text{-et}}/k_{\text{H}}) \} \quad (6)$$

When forward electron transfer is the rate-determining step, $k_{\text{-et}}/k_{\text{H}} \ll 1$, Eq. 6 is reduced to $k_{3\text{H}}/k_{3\text{D}} = 1$. On the other hand, when $k_{\text{-et}}/k_{\text{H}} \gg 1$, Eq. 6 is reduced to $k_{3\text{H}}/k_{3\text{D}} = k_{\text{H}}/k_{\text{D}}$. Thus, the difference between $k_{\text{H}}/k_{\text{D}}$ and $k_{3\text{H}}/k_{3\text{D}}$ should decrease with increasing $k_{\text{-et}}/k_{\text{H}}$. The $k_{\text{-et}}/k_{\text{H}}$ value can be obtained from the $k_{3\text{H}}/k_{3\text{D}}$ and $k_{\text{H}}/k_{\text{D}}$ values by use of Eq. 7, which is derived from Eq. 7 [96]. The $k_{\text{-et}}$ value for back-electron-transfer from $(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}$ to $\text{DMA}^{\cdot+}$:

$$k_{\text{-et}}/k_{\text{H}} = \{ (k_{3\text{H}}/k_{3\text{D}}) - 1 \} / \{ (k_{\text{H}}/k_{\text{D}}) - (k_{3\text{H}}/k_{3\text{D}}) \} \quad (7)$$

is expected to increase with increasing E°_{ox} for DMA, which corresponds to E°_{red} of $\text{DMA}^{\bullet+}$, as the free energy change of back-electron-transfer decreases. The hydrogen atom-transfer rate constant (k_{H}) might be rather insensitive to E°_{ox} compared with the back-electron-transfer rate constant ($k_{\text{-et}}$). In fact, the $k_{\text{-et}}/k_{\text{H}}$ value increases with increasing E°_{ox} , as shown in Figure 1c [96]. Thus comparison of the rate constants for reactions of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ and HRP compound **I** with DMA and analyses of kinetic and product isotope effects clearly indicates that *N*-demethylation of DMA by $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ proceeds via electron transfer from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ followed by hydrogen-atom transfer from $\text{DMA}^{\bullet+}$ to $(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}$ in competition with back-electron-transfer (**C** in Scheme 2). This competition is responsible for the difference between the kinetic and product isotope effects which vary depending on the ratio of the rate constant for back-electron-transfer to that for the hydrogen transfer. The contribution of metal-centered reduction of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ by DMA would give an iron(III)-oxyl radical character $[(\text{TMP})\text{Fe}^{\text{III}}-\text{O}^\bullet]$ (vide supra), which would facilitate hydrogen atom-abstraction from $\text{DMA}^{\bullet+}$.

8.2.5 Electron Transfer Compared with Direct Oxygen Transfer

Comparison of the rate constants of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ and HRP compound **I** was further extended to reactions with a series of sulfides [108]. HRP is known to convert thioanisole to the corresponding sulfoxide [109], although peroxidases typically catalyze two sequential one-electron oxidations such as one-electron oxidation of phenol derivatives to phenoxy radicals [110]. The yield of the sulfoxide from the stoichiometric reaction of HRP compound **I** with thioanisole is only $25 \pm 5\%$. The sulfoxidation involves oxygen-transfer from an oxoferryl species to sulfide, because ^{18}O in $\text{H}_2^{18}\text{O}_2$ has been shown to be incorporated into the product sulfoxide [108, 111]. The initial rapid conversion of compound **I** to compound **II** (k_1) by thioanisole is followed by further reduction to the ferric resting state, as is found for reactions with DMA [108, 112, 113]. A linear correlation between $\log k_1$ and E°_{ox} for the reactions of HRP compound **I** with thioanisoles (Figure 2) is readily combined with the relationship for DMA (Figure 1a) into a single, common relationship (Eq. 8) [108].

$$\log k_1 = -10.5E^\circ_{\text{ox}} + 14.6 \quad (8)$$

Such a unified correlation strongly indicates that the reduction of HRP compound **I** by thioanisoles proceeds via electron transfer rather than direct oxygen transfer. Electron transfer from the sulfide to HRP compound **I** in the protein cage might be followed by two competitive processes: (i) oxygen rebound to afford the sulfoxide; and (ii) diffusion of a sulfenium radical from the protein cage to enable the observation of HRP compound **II** as shown in Scheme 6 [108].

In contrast with the reactions of HRP compound **I** in Figure 2, there is no unified correlation for the reactions of a synthetic model $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}$ with DMA and thioanisoles in plots of $\log k_{\text{obs}}$ against E°_{ox} (Figure 3) [108].

Figure 2. Plots of bimolecular rate constants for the reaction of HRP compound I with DMAs (○) and thioanisoles (●) against the oxidation potentials of DMAs and thioanisoles (E°_{ox}). The slope of the line is shown in parentheses [108].

Scheme 6.

Values of k_{obs} for reactions of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{++}$ with thioanisoles are at least by two-orders of magnitude larger than those for electron transfer from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{++}$. In addition, k_{obs} values of thioanisoles are much less sensitive to E°_{ox} values of thioanisoles compared to the large slope observed for the linear correlation between $\log k_1$ and E°_{ox} for electron transfer from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{++}$. This indicates that the reduction of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{++}$ by thioanisoles proceeds via direct oxygen transfer as shown in Scheme 7 rather than the electron-transfer/oxygen-rebound pathway in Scheme 6 [108].

Figure 3. Plots of bimolecular rate constants for the reaction of compound **I** against the oxidation potentials, E°_{ox} , of DMA and sulfides: $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ with DMAs (\circ) and sulfides (\bullet), His64Ser Mb compound **I** with sulfides (\blacklozenge) [108].

Direct Oxygen Transfer

Scheme 7.

The reactions of compound **I** of a sperm whale myoglobin His64Ser mutant (His64Ser Mb) [114] were also examined to compare the reactivity of His64Ser Mb compound **I** toward thioanisoles with that of the synthetic model $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ [108]. His64Ser Mb compound **I** is readily produced by reaction with *m*CPBA. There is a parallel relationship between the plots for $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ and His64Ser Mb compound **I**, both of which are far above the electron transfer correlation for the reduction of HRP compound **I** by DMA and thioanisoles [108]. This indicates that the reduction of His64Ser Mb compound **I** also proceeds via direct oxygen transfer in Scheme 7 rather than the electron-transfer/oxygen-rebound pathway (Scheme 6) [108].

Comparison of the linear correlation between $\log k_{\text{obs}}$ and E°_{ox} for direct oxygen transfer from $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ to sulfides with that for the electron transfer from DMA to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ in Figure 3 suggests that the relationship for direct oxygen transfer might be included in the relationship for electron transfer when a

sulfide with a lower E°_{ox} value is employed for the reaction with $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$. In such a reaction electron transfer from the sulfide to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ could become preferable to direct oxygen-transfer and an alternation of the reaction mechanism from direct oxygen transfer to electron transfer would occur, depending on the E°_{ox} value. This supposition was demonstrated by use of 1,5-dithiacyclooctane (DTCO), the E°_{ox} value of which is much lower than those of thioanisoles [108]. The k_1 value for the reduction of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ by DTCO becomes even smaller than the value expected from the electron-transfer correlation between $\log k_1$ and E°_{ox} in Figure 3 [108]. Such a small k_{obs} value for DTCO compared with the k_{obs} value for DMA at the same E°_{ox} value is consistent with the larger reorganization energy (λ) expected for electron transfer oxidation producing a σ radical cation (DTCO^{*+}) than the λ values of π radical cations (DMA^{*+}) [18]. Thus reduction of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ by DTCO might proceed via electron transfer from DTCO to $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ rather than direct oxygen transfer.

Alteration of the reaction mechanism from direct oxygen transfer to electron transfer becomes more evident in the reduction of His64Ser Mb compound **I** by DTCO, because rapid formation of compound **II** was clearly observed; this was followed by the slow conversion of compound **II** to the ferric state [108]. The k_{obs} value for electron transfer from DTCO to His64Ser Mb compound **I** agrees with a linear correlation for reactions of $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ with DMA via electron transfer (see Figure 3) [108].

In summary, the reduction of HRP compound **I** and $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ by thioanisoles proceeds via electron transfer whereas the sulfoxidation of thioanisoles with $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ and His64Ser Mb compound **I** occurs via direct oxygen transfer. When thioanisoles are replaced by a much stronger reductant (DTCO), however, the reactions of both $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ and His64Ser Mb compound **I** proceed via electron transfer. The heme group of Mb has been shown to be located close to the protein surface [29, 115–117]; it is therefore more accessible for substrates than the heme group of HRP. Thus reactions of His64Ser Mb compound **I** and synthetic model $[(\text{TMP})\text{Fe}^{\text{IV}}=\text{O}]^{*+}$ can proceed via direct oxygen transfer which requires strong interaction between compound **I** and the substrates rather than electron transfer which can occur at a longer distance for the reactions of HRP compound **I**. When a strong electron donor such as DTCO is employed, the electron-transfer pathway can become energetically preferable to direct oxygen transfer; it can proceed at a long separation distance before interacting strongly with the reaction center.

8.2.6 ‘Agostic’ Interaction

In the hydroxylation of unactivated C–H bonds in hydrocarbons by cytochromes P-450, a hydrogen atom is thought to be abstracted from the substrate C–H bond by a high-valent iron–oxo intermediate, forming a carbon radical which captures an hydroxyl radical from iron (Scheme 8) [27, 118, 119].

This is called an oxygen-rebound mechanism. Large intramolecular isotope effects ($k_{\text{H}}/k_{\text{D}} = 11$) for substrates with CHD groups [120, 121], C–H bond selectivi-

Scheme 8.

ties consistent with those for radical reactions [122] (tertiary > secondary > primary) [123, 124], and loss of stereochemistry in the hydroxylations of norbornane [121, 125] suggest the hydrogen transfer mechanism (Scheme 8). This mechanism was further supported by the detection of rearranged products from carbon radicals in several P-450 oxidations [126]. When, however, the rate constant for the oxygen-rebound step in hydroxylations (k_{reb} in Scheme 8) by a rat liver P-450 isozyme was determined by use of a radical clock substrate [127] widely varying results were obtained (1.4×10^{10} – $1.3 \times 10^{13} \text{ s}^{-1}$) [128–130]. When a hypersensitive radical clock (*trans,trans*-2-*tert*-butoxy-3-phenylcyclopropylmethane) was used to determine the rate constant more accurately it was found that most of the rearranged products were derived from a cationic intermediate produced during the course of the hydroxylation reaction; it was suggested that this process is the origin of the wide variation in the rate constant [131]. The radical species in the hydroxylation reaction was found to have a very short lifetime (70 fs) and it cannot, therefore, be a true intermediate but is part of a reacting ensemble [131]. The small amount of the radical rearrangement product indicates that the rebound step is non-synchronous but concerted with C–H bond cleavage leading to C–O bond formation [131]. The extremely short lifetime of the carbon radical also indicates that the oxygen atom is within bonding distance of carbon at the instant of hydrogen abstraction. This means that a ‘side-on’ approach of oxygen to the C–H bond is favored over the linear C–H–O arrangement of conventional hydrogen-atom abstraction. In addition, the regioselectivity in the reaction of methylcubane with *t*-BuO \cdot has been shown to be quite different from that with cytochrome P-450 enzymes [132]. This is consistent with a concerted mechanism involving ‘side-on’ approach to the C–H bond of the substrate.

Such a ‘side-on’ approach is reminiscent of a three-center two-electron bond, referred to as an agostic interaction [133–136]. An ‘agostic’ substrate–catalyst complex has recently been proposed as a key intermediate before the oxygen-transfer step in the hydroxylation of cyclohexane by PhIO with (TPFPP)FeCl, as shown in Scheme 9 [137].

Substrates such as H₂ which can form strong agostic complexes are expected to inhibit the oxidation of more weakly bound substrates by sequestering the active oxidant (Scheme 9). In fact, the oxidation of cyclohexane was inhibited by the presence of H₂ [137]. On removal of the H₂ from the reaction system, the rate of cyclohexanol production returns to its original value in the absence of H₂, demonstrating that the inhibition is reversible. The pressure at which the rate was half that of the uninhibited reaction ($P_{1/2}$) was 1.4 atm at 0 °C [137]. When H₂ was replaced by D₂, the $P_{1/2}$ value became smaller (1.0 atm) [137]. Such an inverse isotope effect can be compared with the value (0.78) reported for H₂/D₂ binding to a tungsten

Scheme 9.

complex [138]. Methane also inhibits the oxygenation of cyclohexane, possibly because of formation of a complex with $[(\text{TPFP})\text{Fe}^{\text{IV}}=\text{O}]^+$. It has been shown that even heptane can coordinate to iron(II) with a double A-frame porphyrin and that the metal-to-carbon distances determined by X-ray analysis are 2.5–2.8 Å, typical of moderate to weak agostic interaction [139]. Results from density-functional calculations on iron porphyrin complexes of methane and ethane are indicative of significant charge-transfer character of the complexes (e.g. 0.23 e for ethane) in which the alkane acts as an electron donor [139]. Thus, a charge-transfer-type interaction might play an important role in the ‘agostic’ substrate-catalyst complex in Scheme 9. Although the importance of charge-transfer complexes as intermediates in a variety of redox reactions has been well documented [83, 140–145], the ‘agostic’ substrate–catalyst complex proposed in Scheme 9 has yet to be characterized [137].

8.2.7 Site of Electron Transfer in Compound I

Electron-transfer reactions between cytochrome *c* and cytochrome *c* peroxidase have been studied extensively because of the well-characterized structures and biophysical properties of the reactants [146–150]. It is well known that the resting ferric form of cytochrome *c* peroxidase is oxidized by hydrogen peroxide to compound **I**, which contains an oxyferryl heme moiety in which the iron atom has a formal oxidation state of 4+ [146–150]. The other is a porphyrin π radical cation or organic radical (R^+) localized on an amino acid residue of Trp-191 [151–154]; this is formed by transfer of the oxidized equivalent to the amino acid side chain [150]. The site of electron transfer in the reduction of compound **I** has been controversial and two forms of compound **II** have been identified, $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$ containing the oxyferryl heme $\text{Fe}(\text{IV})$ [155–158] and $[(\text{P})\text{Fe}^{\text{III}}]^{\cdot 2+}$ containing $\text{Fe}(\text{III})$ and the porphyrin π radical cation which oxidizes the amino acid side-chain to produce an organic radical $[(\text{P})\text{Fe}^{\text{III}}]^+, \text{R}^+$ [159–165] as shown in Scheme 10.

These two pathways have been shown to be affected by ionic strength (μ) [166]. At low ionic strength (below $\mu = 50$ mM) the $\text{Fe}(\text{IV})$ site of compound **I** is preferentially reduced, followed by reduction of the radical site in the slow phase of the reaction [166]. At high ionic strength (e.g. $\mu = 200$ mM), the radical site is preferentially reduced, giving a compound **II** that retains the $\text{Fe}(\text{IV})$ site [166]. The switch of the site of electron transfer between the $\text{Fe}(\text{IV})$ site and the radical site seems to

Scheme 10.

be controlled by the orientation of the two proteins in the complex, which depends on ionic strength [147]. In yeast cytochrome c-peroxidase complex crystallized at high ionic strength, a short electron transfer pathway from heme to Trp-191 becomes available; there is more intimate contact between cytochrome c and the peroxidase for the complex crystallized at low ionic strength [147]. It was suggested that at low ionic strength the orientation was dominated by electrostatic forces and that at high ionic strength the orientation was dominated by the hydrophobic interaction [166].

8.2.8 Photoinduced Electron-transfer Oxidation

The fast oxidation processes of HRP and its functional model peptides [microperoxidase-8 (MP8)] generating the corresponding compound I ($[(\text{P})\text{Fe}^{\text{IV}}\text{=O}]^{\bullet+}$) and compound II ($[(\text{P})\text{Fe}^{\text{IV}}\text{=O}]$) have been successfully monitored by use of laser-flash photolysis [167, 168]. The photocatalytic system for generation of HRP compound I and compound II is shown in Scheme 11 [168].

The MLCT (metal to ligand charge transfer) excited state of $[\text{Ru}(\text{bpy})_3]^{2+*}$ ($[\text{Ru}(\text{bpy})_3]^{2+*}$) is produced by irradiation with visible light; electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to the Co^{III} complex gives $[\text{Ru}(\text{bpy})_3]^{3+}$ [168]. The oxidizing power of $[\text{Ru}(\text{bpy})_3]^{3+}$ is sufficient to oxidize the ferric resting state of HRP ($[(\text{P})\text{Fe}^{\text{III}}]^+$) at the ligand center to give the porphyrin π radical cation ($[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$). This step is followed by the slower step of conversion of $[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$ to compound II, $(\text{P})\text{Fe}^{\text{IV}}\text{=O}$, accompanied by deprotonation of the coordinated water [168].

The kinetics at 430 nm after a laser flash of the photocatalytic system (pH 8.5) in Scheme 11 are biphasic—a fast reaction on a millisecond time-scale because of formation of $[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$ was followed by a much slower reaction on a second time-scale because of the conversion of $[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$ to compound II, $(\text{P})\text{Fe}^{\text{IV}}\text{=O}$ [168]. In general, ferric porphyrins have ligand-centered one-electron oxidation potentials at which ferric porphyrins are oxidized to ferric porphyrin π radical cations; these are higher than oxidation potentials for metal-centered one-electron oxidation to ferryl porphyrins [102, 170]. Despite the smaller (by ca 0.3 eV) driving force for ligand-centered oxidation than for metal-centered oxidation [102, 170], ligand-centered oxidation of HRP occurs before metal-centered oxidation (Scheme 11). This is be-

Scheme 11.

cause ligand-centered oxidation requires a much smaller reorganization energy for electron transfer and it is, therefore, kinetically favored—as seen in the electron-transfer oxidation of (P)Fe(R) [93]. Only the first process requires [Ru(bpy)₃]³⁺, which was reduced to [Ru(bpy)₃]²⁺. The formation of [Ru(bpy)₃]²⁺ was readily monitored at 450 nm. The rate of formation of [(P)Fe^{III}]^{•2+} shows first-order dependence on the [Ru(bpy)₃]³⁺ concentration (Eq. 9), whereas conversion to compound **II** is first-order with respect to [(P)Fe^{III}]^{•2+} concentration (Eq. 10). The rate constant (*k*_{et1}) for electron transfer from [(P)Fe^{III}]^{•+} to [Ru(bpy)₃]³⁺ was determined as $2.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ at pH 10.3 [168]. The rate constant (*k*_{et2}) for generation of (P)Fe^{IV}=O at pH 10.8 ($95 \pm 7 \text{ s}^{-1}$) is over 20 times larger than that at lower pH ($4.1 \pm 0.9 \text{ s}^{-1}$) [168].

$$d[(P)Fe^{III} \cdot 2+]/dt = k_1[(P)Fe^{III} +][Ru(bpy)_3]^{3+} \quad (9)$$

$$d[(P)Fe^{IV}=O]/dt = k_2[(P)Fe^{III}]^{2+} \quad (10)$$

In acidic solutions ferric MP8 is also rapidly oxidized by $[\text{Ru}(\text{bpy})_3]^{3+}$ to a ferric porphyrin π radical cation; the rate constant $k_{\text{etI}} = 5.6 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ which is much larger than the value for HRP [167]. In alkaline solutions, the oxidation product is ferryl MP8 which is represented as a generalized form, $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$. In this instance, however, transformation of $[(\text{P})\text{Fe}^{\text{III}}]^{2+}$ to $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$ was too fast to be detected [167].

In contrast with HRP, P-450 cannot be oxidized efficiently by external redox agents such as $[\text{Ru}(\text{bpy})_3]^{3+}$, because heme is deeply buried in P-450 [169]. By tethering a $[\text{Ru}(\text{bpy})_3]^{2+}$ photosensitizer to a protein substrate through a hydrocarbon chain, however, the heme porphyrin π radical cation or the Fe^{IV} species which corresponds to compound **II** has been detected successfully upon laser photolysis of the $[\text{Ru}(\text{bpy})_3]^{2+}$ -tethered P-450 in the presence of $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$ [169].

HRP compound **II** is further oxidized by electron transfer with $[\text{Ru}(\text{bpy})_3]^{3+}$ to afford compound **I** (Scheme 11) [168]. Compound **II** was generated spontaneously after photolysis of the HRP- $[\text{Ru}(\text{bpy})_3]^{2+}$ - $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$ system [168]. The rate of formation of compound **I** obeys second-order kinetics, being first order in each reactant, as given by Eq. 11 [168].

$$d[(\text{P})\text{Fe}^{\text{IV}}=\text{O}]^{\bullet+}/dt = k_{\text{et}}[(\text{P})\text{Fe}^{\text{IV}}=\text{O}][[\text{Ru}(\text{bpy})_3]^{3+}] \quad (11)$$

The rate constant for electron transfer from HRP compound **II** to $[\text{Ru}(\text{bpy})_3]^{3+}$ is nearly independent of pH. Although the k_{et} value ($1.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) is slightly larger than the value for formation of $[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$ ($2.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) at pH 10.3, the k_{et} value ($1.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) is significantly smaller than the value ($5.6 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) for the porphyrin ligand-centered oxidation of ferric MP8 by $[\text{Ru}(\text{bpy})_3]^{3+}$, despite the higher driving force for electron transfer from HRP compound **II** to $[\text{Ru}(\text{bpy})_3]^{3+}$ ($\Delta G^\circ_{\text{et}} = -8.1 \text{ kcal mol}^{-1}$ obtained from the E°_{ox} value of HRP compound **I**, which is equal to E°_{red} of HRP compound **II** [104], and the E°_{red} value of $[\text{Ru}(\text{bpy})_3]^{3+}$) [171]. When the Marcus theory (Eq. 4) [91] is applied to the k_{et} value ($1.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$), the λ value is evaluated as $\lambda = 30.2 \text{ kcal mol}^{-1}$. If the reorganization energy for electron self-exchange between $[\text{Ru}(\text{bpy})_3]^{3+}$ and $[\text{Ru}(\text{bpy})_3]^{2+}$ is neglected [93], a large λ value ($60.4 \text{ kcal mol}^{-1}$) is obtained for the electron self-exchange between HRP compound **I** and compound **II**, because the λ value for the cross reaction is equal to the average of the λ value for electron self-exchange for each reactant. This value is quite consistent with a large reorganization energy ($\lambda = 61.9 \text{ kcal mol}^{-1}$) [104] derived from the electron-transfer rate from ferrocyanide to HRP compound **I** (vide supra). Such a large λ value for electron self-exchange between HRP compound **I** and compound **II** and the slower rate than that for the purely ligand-centered oxidation of ferric MP8, despite the larger driving force, is indicative of a significant contribution from the metal-centered oxidation of HRP compound **II** rather than the porphyrin ligand-centered oxidation. This means that HRP compound **II**, formally $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$ should contain a significant amount of $(\text{P})\text{Fe}^{\text{III}}-\text{O}^\bullet$ character, as discussed in the section on P-450 reaction mechanisms (vide supra).

Stepwise conversion of $[(\text{P})\text{Fe}^{\text{III}}]^{\bullet+}$ to $(\text{P})\text{Fe}^{\text{IV}}=\text{O}$ has been clearly shown by cofactor reconstitution and use of myoglobin (Mb) bearing a ruthenium complex $[\text{Ru}(\text{bpy})_3-\text{Mb}]$ (see Scheme 12) [172].

The reconstitution of chemically modified heme with apo-Mb has been well established [173–176]. The one-electron reduction potential of ferryl-Mb (Fe^{IV} -heme) was reported as 0.896 V relative to the NHE [177] which is less positive than the one-electron oxidation potential of $[\text{Ru}(\text{bpy})_3]^{2+}$ (1.25 V). Thus, generation of ferryl-Mb by electron transfer from the met-Mb (ferric state) moiety to the Ru^{3+} moiety might be thermodynamically favorable. An appropriate amount of a sacrificial electron acceptor such as $[\text{Co}(\text{NH}_3)_3\text{Cl}]^{2+}$ which can quench the Ru^{2+} excited state oxidatively was, however, required to produce the Ru^{3+} state in competition with the reductive quenching of the Ru^{2+} excited state by the met-Mb [178, 179]. No direct electron transfer from the met-Mb (ferric state) moiety to the Ru^{2+} excited state occurs, because this process is thermodynamically disfavored [178, 179].

Scheme 12.

Steady-state irradiation with visible light of a deaerated aqueous solution containing Ru(bpy)₃-met-Mb in the presence of [Co(NH₃)₅Cl]²⁺ at pH = 7.5 results in the formation of ferric-Mb [172] which has a strong absorption maximum at 408 nm with weak peaks at 505 and 630 nm [180]. No reaction occurred at pH < 6. Laser-flash photolysis study has revealed that the Ru²⁺ excited state is oxidatively quenched by [Co(NH₃)₅Cl]²⁺ (3 mM) within 0.04 μs in competition with the reductive quenching by met-Mb. Simple bleaching of a Soret band region as a result of formation of the ferric porphyrin π radical cation [181] was detected 1 μs after the laser pulse; this rapid reaction was followed by the appearance of a new peak, from ferryl-Mb, at 426 nm. The rate constants for the first and second stages were determined as 7.1 × 10⁵ s⁻¹, and 4.0 × 10⁴ s⁻¹, respectively [172]. The rate constant for electron transfer from the met-Mb to the Ru³⁺ state (first stage) is independent of pH whereas that for transformation from the ferric porphyrin π radical cation to the ferryl-Mb (second stage) is dependent on pH and the value increased from 4.0 × 10⁴ s⁻¹ at pH 7.5 to 2.0 × 10⁵ at pH 9.0, as expected from the concomitant deprotonation of coordinated water to generate the ferryl-Mb [172].

8.2.9 Oxygen-evolving Complex

Four-electron oxidation of water to oxygen in photosystem II (PSII) is catalyzed by the oxygen-evolving complex (OEC) which contains a tetranuclear manganese cluster as the active site of water oxidation in photosynthetic organisms [182–184]. Extensive efforts have been devoted to developing synthetic models of OEC [185–189], but only rarely have the model complexes actually catalyzed water oxidation [190–195]. The first example of a manganese-based homogeneous catalyst for the oxidation of water is the dimanganese complex of cofacial dimers of triphenylporphyrin linked by an *o*-phenylene bridge, as shown in Scheme 13 [190].

Scheme 13.

Anodic oxidation of an aqueous acetonitrile solution in the absence of the manganese porphyrin dimers did not result in evolution of oxygen at potentials up to +2.3 V (relative to Ag/Ag^+), whereas electrochemical oxidation in the presence of the dimer resulted in oxygen evolution at potentials between +1.2 and +2.0 V with a faradaic efficiency of 5–17 % [190]. The maximum turnover number (mol O_2 /mol catalyst) was 9.2 when a manganese porphyrin dimer with $R = \text{C}_6\text{F}_5$ in Scheme 13 was employed as a catalyst at 2.0 V in the presence of $n\text{-Bu}_4\text{NOH}$ [190]. It was confirmed that the rate of oxygen evolution was proportional to catalyst concentration and, on the basis of a labeling experiment using H_2^{18}O , that the O_2 evolved came from H_2O [190]. Although the catalytic mechanism remains to be clarified, it is proposed that OH^- might coordinate to each Mn ion of the dimer inside the cavity and that four-electron oxidation at the electrode gives $\text{Mn}^{\text{IV}}=\text{O}$ dimer in which the O–O bond is formed efficiently to afford an $\text{Mn}^{\text{IV}}\text{--O--O--Mn}^{\text{IV}}$ complex because of the proximity of two Mn ions. The peroxy bridge could then be replaced by an OH^- ion, evolving O_2 and accompanied by regeneration of the Mn^{III} dimer (Scheme 13) [190].

Similar manganese porphyrin dimers linked by different spacer molecules had catalase activity [196]. The activity was highest when the Mn–Mn separation was ca 4 Å, in agreement with the Mn–Mn separation in the hypothetical $\text{Mn}^{\text{IV}}\text{--O--O--Mn}^{\text{IV}}$ complex [196]. The high-valent Mn porphyrin dimer has been prepared by the oxidation of the Mn^{III} dimer with *m*CPBA. The Mn^{IV} dimer thus formed was stable for hours at temperatures ranging from -78 to -20°C and it was detected by ESI MS (electrospray ionization mass spectroscopy) [197]. Cyclooctene was oxidized by *m*CPBA (1.1 equivalent for each Mn ion) with the Mn^{III} dimer to

yield the epoxide in 41 % yield on the basis of the amount of *m*CPBA [197]. After the reaction, the Mn complex was recovered in the Mn^{IV} state [197]. This indicates that only one $\text{Mn}^{\text{IV}}=\text{O}$ in the dimer was effective in the epoxidation and that another equivalent of the oxidant was consumed in conversion of the Mn^{III} to the Mn^{IV} dimer [197].

The first clear example of an O–O bond-forming reaction involving a di- μ -oxo dimanganese complex has recently been reported for the $\text{Mn}(\text{III})$ – $\text{Mn}(\text{IV})$ complex, $[\text{H}_2\text{O}(\text{terpy})\text{Mn}(\text{O})_2\text{Mn}(\text{terpy})\text{OH}_2](\text{NO}_3)_3$ (terpy is 2,2':6',2''-terpyridine) [194]. The X-ray structure was well-characterized and revealed a di- μ -oxo core with dimensions typical of such complexes (2.7 Å for the Mn–Mn distance) [194]. An ESR spectrum of the di- μ -oxo dimanganese complex contained 16 lines characteristic of $\text{Mn}(\text{III})$ – $\text{Mn}(\text{IV})$ mixed valence dimers [198]. Water is oxidized to O_2 by NaClO in the presence of the di- μ -oxo dimanganese complex. An ^{18}O -labeling experiment indicated the participation of $\text{Mn}^{\text{IV}}=\text{O}$ species in the water oxidation, as shown in Scheme 14. The first step is the formation of a $\text{Mn}^{\text{V}}=\text{O}$, in which the O atom originates from $^{16}\text{OCl}^-$. The terminal oxo ligand can rapidly exchange with an ^{18}O -labeled hydroxide or aqua ligand on the other Mn ion of the di- μ -oxo dimanganese complex. The ^{16}O -hydroxide/aqua ligand can then exchange rapidly with the solvent, to produce a complex in which where both Mn sites are ^{18}O labeled, to yield $^{18}\text{O}_2$ (Scheme 14) [194].

Unfortunately, however, the catalytic reactions end with the complete conversion of the Mn to permanganate after ca 6 h [194]. The detailed mechanism for the catalytic oxidation of water remains to be clarified.

Scheme 14.

8.3 Catalytic Reduction of Oxygen

The reverse reaction of the oxidation of water to oxygen described above is four-electron reduction of O_2 to H_2O by cytochrome c oxidases; this is the key step in the

respiratory storage of metabolic energy as ATP (adenosine triphosphate) [199–203]. The most important feature of cytochrome c oxidases is that they do not release one-electron or two-electron reduced products (O_2^- and H_2O_2 , respectively) both of which would be toxic and devastating to the cell [199–203]. To understand the catalytic mechanism of the four-electron reduction of O_2 considerable efforts have long been made to prepare synthetic analogs of the active center of cytochrome c oxidases [204–207]. Studies on cytochrome c oxidases and the model complexes have recently been stimulated by the publication of X-ray structures of cytochrome c oxidases [208–212]. Cytochrome c oxidase has a heteronuclear heme $\text{a}_3/\text{Cu}_\text{B}$ metal center in which a myoglobin-type iron center and a copper atom (Cu_B) coordinate to three imidazoles from histidine residues on the distal side [208–212]. A Cu(II) binding site has recently been constructed successfully by use of cytochrome c peroxidase mutant (Arg48His, Trp51His, His52Ala, Ser81His) from yeast mitochondria [213]. Two other metal sites, a coordinately saturated heme and a dinuclear Cu_2 center are involved in storing and transferring the electrons during the four-electron reduction of O_2 [208–212]. Although many issues still remain to be resolved, particularly the exact role of Cu in the catalytic cycle, ongoing research on cytochrome c oxidase model systems has provided valuable mechanistic insight into the catalytic mechanism of the four-electron reduction of O_2 as described below.

8.3.1 Two-electron Reduction

Even simple metalloporphyrins such as $[(\text{TPP})\text{M}]^+$ where $\text{M} = \text{Co}$, Fe and Mn can enable reduction of O_2 to H_2O by ferrocene derivatives (Fc) used as an electron donor in the presence of HClO_4 in acetonitrile [214, 215]. However, the rate-determining step is the two-electron reduction of O_2 to H_2O_2 (Scheme 15) [214, 125]. Nonetheless, the catalytic effect of $[(\text{TPP})\text{M}]^+$ for the reduction of O_2 by Fc is remarkable, because the oxidation of ferrocene by O_2 hardly occurred in the presence of HClO_4 without $[(\text{TPP})\text{M}]^+$ [216]. The rate-determining step for the $[(\text{TPP})\text{M}]^+$ -catalyzed two-electron reduction of O_2 to H_2O_2 has been shown to be the initial electron transfer from Fc to $[(\text{TPP})\text{M}]^+$ as shown in Scheme 15 [215]. The reduced metalloporphyrin, $(\text{TPP})\text{M}$, is rapidly oxidized by acid-catalyzed electron-transfer reduction of O_2 by Fc, regenerating $[(\text{TPP})\text{M}]^+$ via formation of the putative hydroperoxo complex (Scheme 15) [215].

The rate constants (k_et) of electron transfer from Fc to $[(\text{TPP})\text{M}]^+$ agree well with those evaluated in light of the Marcus equations [91] for outer-sphere electron transfer (Eq. 4) [215]. Such agreement clearly demonstrates that electron transfer from Fc to $[(\text{TPP})\text{M}]^+$ in Scheme 15 proceeds via an outer-sphere pathway. In contrast to this, the k_et value of the acid-catalyzed electron transfer from $(\text{TPP})\text{Co}$ to O_2 is 10^9 -fold larger than that expected from an outer-sphere electron transfer [215]. Such huge enhancement of the observed rate relative to that calculated for outer-sphere electron transfer indicates the strong inner-sphere nature of acid-catalyzed electron transfer from $(\text{TPP})\text{Co}$ to O_2 ; this should result in formation of the hydroperoxo complex, $[(\text{TPP})\text{CoO}_2\text{H}]^+$ (Scheme 15, $\text{M} = \text{Co}$). Other metalloporphyrins ($\text{M} = \text{Fe}$ and Mn) can also act as efficient catalysts of the reduction of

Scheme 15.

O_2 by Fc in the presence of HClO_4 in acetonitrile. The inner-sphere nature of the acid-catalyzed electron transfer from $(\text{TPP})\text{M}$ to O_2 is essential to the catalytic cycle. Otherwise $[(\text{TPP})\text{M}]^+$ would act solely as an electron mediator and no acceleration of the overall electron transfer from Fc to O_2 would be achieved.

An NADH analog, 10-methyl-9,10-dihydroacridine (AcrH_2) can also reduce O_2 to H_2O in the presence of a catalytic amount of $[(\text{TPP})\text{M}]^+$ ($\text{M} = \text{Co}, \text{Fe}$) in the presence of HClO_4 in MeCN [217, 218]. In this instance also the two-electron reduction of O_2 to H_2O_2 is the rate-determining step. The catalytic two-electron reduction of O_2 by AcrH_2 also proceeds via electron transfer from AcrH_2 to $[(\text{TPP})\text{M}]^+$ in the presence of O_2 and HClO_4 to produce a radical pair ($\text{AcrH}_2^{\cdot+} [(\text{TPP})\text{CoO}_2\text{H}]^{\cdot+}$) followed by hydrogen transfer from $\text{AcrH}_2^{\cdot+}$ to $[(\text{TPP})\text{MO}_2\text{H}]^{\cdot+}$ to yield 10-methylacridinium ion (AcrH^+) and H_2O_2 , accompanied by regeneration of $[(\text{TPP})\text{M}]^+$ (Scheme 16) [218].

The kinetic isotope effect ($k_{\text{H}}/k_{\text{D}} = 7.1$) observed when AcrH_2 is replaced by AcrD_2 is ascribed to this hydrogen-transfer step [218].

To achieve the four-electron reduction of O_2 to H_2O without releasing H_2O_2 another metal ion such as Cu ion in cytochrome c oxidase is required to stabilize the two-electron reduced peroxy species by forming a bimetallic peroxo complex. This

Scheme 16.

would make the release of peroxide unfavorable, resulting in the direct four-electron reduction of O_2 to H_2O . The initial electron transfer to O_2 is also accelerated by the interaction of O_2^- with a metal ion which can act as a Lewis acid. Such catalysis of metal ions to accelerate the electron-transfer reduction of a variety of substrates, including oxygen, has been well documented [219, 220]. The existence of a strong interaction between O_2^- and Sc^{3+} has been demonstrated by observation of the ESR spectrum of the $\text{O}_2^- - \text{Sc}^{3+}$ complex [221]. The $\text{O}_2^- - \text{Sc}^{3+}$ complex is generated by photoinduced electron transfer from the dimeric 1-benzyl-1,4-dihydronicotinamide $[(\text{BNA})_2]$, which can act as a unique two-electron donor [222, 223], to O_2 [221]. The clear eight-line isotropic spectrum at the center is ascribed to the superhyperfine coupling of O_2^- with the 7/2 nuclear spin of the scandium nucleus ($a_{\text{Sc}} = 3.82 \text{ G}$) [221]. The isotropic g value (2.0165) is appreciably smaller than the average value (2.030) [224] of the principal three g components of O_2^- at 77 K, being consistent with spin delocalization to the scandium nucleus, as demonstrated by observation of the superhyperfine coupling. The two inequivalent $a(^{17}\text{O})$ values (21 and 14 G) observed for the $\text{O}_2^- - \text{Sc}^{3+}$ complex containing ^{17}O are fully consistent with 'end-on' coordination form of $^{\cdot}\text{O}-\text{O}^- - \text{Sc}^{3+}$ in which the electron spin is more localized at the terminal oxygen [221].

8.3.2 Four-electron Reduction

Several dimeric metalloporphyrins [225–230] have been used to achieve four-electron reduction of O_2 to H_2O . The binding of O_2 to the metal center inside the cavity of two porphyrins seems to be essential for the four-electron reduction of O_2 to H_2O as shown in Scheme 17 [230].

When O_2 binds the Co(II) center of the bisporphyrin inside the cavity to produce the *endo* complex (path a), the superoxo complex interacts strongly with the Sc(III) ion, leading to the further reduction to H_2O via the corresponding peroxo complex in which the interaction with Sc(III) becomes much stronger. Heterolytic cleavage

Scheme 17.

of the O–O bond can then occur, followed by a further two-reduction to yield H_2O . When the Co(II) center binds O_2 outside the cavity, however, there is no interaction of the superoxo complex with the Sc(III) ion (path **b**). Then protonation predominates, followed by the further one-electron reduction to yield H_2O_2 .

Several heterodinuclear Fe–Cu or Co–Cu complexes that closely resemble the native enzyme active sites have recently been prepared to elucidate the catalytic mechanism of cytochrome c oxidases [231–245]. The use of a covalently attached axial ligand seems essential to achieve efficient electroreduction of O_2 to H_2O [235, 238, 241–243]. The closest structural analogs of the heme a_3/Cu_B active site of cytochrome c oxidases reported so far are Fe–Cu complexes (**1** and **2**) in which the Cu coordination site is provided by three imidazole ligands [242]. These biomimetic model complexes afford clean electroreduction of O_2 to H_2O over a wide range of pH with no leakage of H_2O_2 [243].

The acetamide linkages in **1** and **2** provide enough flexibility to the distal imidazole ligands, and they are short enough to keep Cu–Fe distance within the 4.5–5.5 Å range, but not to coordinate to the iron atom [242]. Oxygen binds irreversibly with **1** or **2** to form a putative peroxo- $\text{Fe}^{\text{III}}(\text{O}^{2-})\text{Cu}^{\text{II}}$ intermediate, which is too unstable to be characterized [243].

Extensive efforts have been made to identify the active oxygen intermediates during the catalytic reduction of O_2 to H_2O by cytochrome c oxidases, although the characterization of the active oxygen intermediates remains to be fully understood [246–248]. A stable peroxo $\text{Fe}^{\text{III}}\text{–Cu}^{\text{II}}$ complex (**4**) has been reported to be formed by the reaction of a $\text{Fe}^{\text{II}}\text{–Cu}^{\text{I}}$ complex (**3**) with O_2 (Scheme 18); this complex was characterized spectroscopically [237].

The ESI mass spectrum in MeCN gives a peak at $m/z = 1094$ and the isotope pattern expected from a monocation **4** [237]. The observed Raman band indicates a peroxo O–O stretching vibration at 803 cm^{-1} which is shifted to 759 cm^{-1} on use of $^{18}\text{O}_2$ ($\Delta^{16}\text{O}_2/^{18}\text{O}_2 = 44\text{ cm}^{-1}$) [237, 247]. The peroxo complex **4** is ESR silent,

Scheme 18.

which is indicative of strong magnetic coupling between the two metals [237]. These results suggest that the peroxo ligand in **4** is bridging in end-on fashion, as shown in Scheme 18, rather than side-on fashion [237]. However, a side-on coordination mode is also possible for other Cu-Fe bimetallic peroxide complexes with different ligands [241, 244]. The magnetic properties and reactivities of Cu-Fe bimetallic peroxide complexes have been shown to be altered drastically by subtle changes of ligand architecture [244]. The electron-transfer properties of this new type of O₂ adduct remain to be clarified.

8.4 Electron Transfer in Organized Media

When porphyrins and metalloporphyrins are placed with suitable redox couples in organized media, biomimetic electron-transfer systems involving the redox-active porphyrins can be constructed to achieve catalytic redox reaction and vectorial electron transport [249–254]. The biomimetic examples include Langmuir–Blodgett films [255–265], lipid bilayer membranes [266–284], micelles [285–292], vesicles [293–298], self-assembled monolayers [299–339], and others [340, 341]. The covalent attachment of a porphyrin to a donor and/or an acceptor enhances the electronic coupling between the porphyrin and the redox couples through the bridge, with the result that intramolecular electron transfer predominates over an intermolecular electron transfer. Thus, incorporation of the porphyrin-containing dyads and the more sophisticated systems into the organized media seems to be promising for the realization of molecule-based catalysis and artificial photosynthetic materials in which the occurrence of efficient electron transfer is the heart of the strategy. This section focuses on self-assembled monolayers of porphyrin-containing systems, which have been developed intensively during the recent years, although a variety of important studies from other areas is also reported.

8.4.1 Electrocatalysis of Self-assembled Monolayers of Porphyrins

Self-assembled monolayers have recently attracted much attention as a new methodology for molecular assembly [249, 342]. They enable highly organized chemical binding of molecules of interest to the surfaces of, e.g., metals, semiconductors, and insulators. The well-ordered structure of self-assembled monolayers is in sharp contrast with conventional Langmuir–Blodgett films and lipid bilayer membranes in terms of stability, uniformity, and manipulation. Functional molecules can be arranged unidirectionally at the molecular level on substrates when substituents which will self-assemble on the substrates are attached to a terminal of the molecules. The wide variety of examples reported to date include porphyrins and metalloporphyrins in self-assembled monolayers [299–339].

One of the first reported self-assembled monolayers of porphyrins is cobalt(II)-porphyrins **5** and **6** and the analog free-base porphyrins **7** and **8**, in which the number and location of the thiol-containing tails are varied systematically [300, 314].

Electrochemical data indicate that self-assembled monolayers of **5** and **6** catalyze the two-electron reduction of O₂ to H₂O₂. The monolayer from **6** is a more effective electrocatalyst for the reduction of O₂ than that from **5** [300]. The different reactivity results from different interfacial architecture; this is confirmed by infrared, X-ray photoelectron, and visible spectroscopic measurements [300] which revealed coplanar, inclined π – π stacking of the porphyrin ring in the monolayer of **5** and head-to-tail orientation of the porphyrin ring in the monolayer of **6**. Treatment of the monolayer of **8** with Co(OAc)₂ in methanol resulted in electrocatalytic activity in the reduction of O₂ [300]. In contrast, a monolayer of **7** treated similarly failed to catalyze dioxygen reduction [300], although treatment of a mixed monolayer of **7** and CH₃(CH₂)₃SH with Co(OAc)₂ results in electrocatalytic activity similar to that of **6**.

A tetraphenylporphyrin derivative with four thiol moieties **9** and a similar bis(cobalt) cofacial diporphyrin with three thiol moieties **10**, prepared independently at the same time, electrocatalytically reduce O_2 on a variety of gold surfaces [301, 316].

Cyclic voltammetric and X-ray photoelectron spectroscopic measurements showed the formation of nearly one monolayer where the porphyrin rings with thiol groups are coplanar to the electrode surface through two or three S–Au linkages per porphyrin [301, 316]. The value (Γ) of surface coverage for **9** was determined to be $7.2\text{--}8.6 \times 10^{-11} \text{ mol cm}^{-2}$ ($190\text{--}230 \text{ \AA}^2 \text{ molecule}^{-1}$). This value is quite consistent with a preference for orientation of the porphyrin ring coplanar with the gold surface ($262 \text{ \AA}^2 \text{ molecule}^{-1}$). Self-assembled monolayers of **9** and **10** afforded two-electron reduction of O_2 to H_2O_2 . This is in sharp contrast with the electrocatalytic activity of **10** chemisorbed on an edge-plane pyrolytic graphite electrode in which the four-electron reduction of O_2 was achieved [225–227, 343–346]. These results indicate that the edge-plane graphite surface plays a crucial role in biomimetic catalysis of the four-electron reduction of O_2 .

Self-assembled monolayers of metalloporphyrins **11–16**, similar to **5** and **7**, have also been constructed on gold surfaces [307, 335]. The Γ value of surface coverage was estimated to be $3.8 \times 10^{-10} \text{ mol cm}^{-2}$ ($44 \text{ \AA}^2 \text{ molecule}^{-1}$), suggesting closely packed structures of the porphyrin with perpendicular orientation to the gold surface [335]. The insertion of the metal ion into a self-assembled monolayer of free base porphyrin **17** on the gold surface has been performed by refluxing the metal ion solution in which the modified gold electrode was immersed [335].

The extent of metal insertion is strongly dependent on the type of metal ion. Cobalt (II), nickel (II), and zinc (II) are readily incorporated into the porphyrin ring, whereas manganese (II), iron (II), and copper (II) are difficult to insert under the same experimental conditions [335]. Self-assembled monolayers of **12** and **13** have electro-catalytic activity in the reduction of O_2 to H_2O and H_2O_2 , respectively.

11: M=Mn(II); **12:** M=Fe(II); **13:** M=Co(II); **14:** M=Ni(II);
15: M=Cu(II); **16:** M=Zn(II); **17:** M=H₂

Although mechanistic aspects of electron transfer in these systems remains ambiguous, catalysts self-assembled on the gold surface are amenable to the surface analysis as compared with those immobilized on conventional electrodes. More detailed studies including elaborate molecular design are required to elucidate the relationship between the interfacial structure and the electrocatalytic function.

8.4.3 Photoinduced Electron Transfer of Metalloporphyrins in Self-assembled Monolayers

Photoinduced electron-transfer reactions on gold electrodes modified with porphyrins and metalloporphyrins have been extensively studied to enable the development of molecular devices for solar-energy conversion and of photonic sensors [302, 305, 309–312, 318–320, 323, 325, 327–329, 331–334, 336, 338, 339]. Systematic studies on the structure and photoelectrochemical properties of the self-assembled monolayer of porphyrins **18** on a gold electrode have been reported to clarify the effects of the spacer length [302, 325, 338]. In the molecular design of **18**, six *t*-butyl groups were introduced into *meso*-phenyl rings of the porphyrin moiety to increase solubility in organic solvents and to suppress the quenching of the excited states of the porphyrins in the monolayers because of the porphyrin aggregation (Scheme 19) [347].

The structure of the self-assembled monolayers was investigated by use of ultraviolet–visible absorption spectroscopy in transmission mode, cyclic voltammetry, ultraviolet–visible ellipsometry, and fluorescence spectroscopy [338]. These experiments showed that as the length of the spacing methylene chain was increased the self-assembled monolayers tended to form highly ordered structures on the gold electrode, with surface coverage reaching 1.5×10^{-10} mol cm⁻² (110 Å² molecule⁻¹) [338]. Adjacent porphyrin rings take J-aggregate-like partially stacked struc-

Scheme 19.

tures in the monolayer [338]. The porphyrin ring plane in the monolayer with an even number ($n = 2, 4, 6, 10$) of methylene spacers ($-(\text{CH}_2)_n-$) is tilted significantly to the gold surface, whereas porphyrins with odd numbers ($n = 1, 3, 5, 7, 11$) of methylene spacers adopt nearly perpendicular orientation to the gold surface [338].

Photoelectrochemical studies of gold electrodes modified with **18** were performed in an argon-saturated Na_2SO_4 aqueous solution containing methyl viologen as an electron carrier and using a platinum wire counter electrode and a Ag/AgCl reference electrode [338]. An increase in the cathodic photocurrent was observed on increasing the negative bias (from 700 mV to -200 mV) relative to the gold electrode [338]. This indicates that the vectorial photocurrent flows from the gold electrode to the counter electrode through the monolayer and the electrolyte. The quantum yield for photocurrent generation increases in a zigzag fashion with increasing spacer length up to $n = 6$ (ca 0.3 %) and then starts decreasing with a further increase in the spacer length. Such dependence of the quantum yield on spacer length can be explained by competition between electron transfer and energy transfer of the singlet excited state of the porphyrin as shown in Scheme 19.

Photoirradiation of the modified electrode results in electron transfer from the singlet excited state of the porphyrin ($E^\circ_{\text{ox}} = -0.80$ V ($n = 11$) relative to Ag/AgCl) to the methyl viologen ($E^\circ_{\text{red}} = -0.62$ V relative to Ag/AgCl) or O_2 ($E^\circ_{\text{red}} = -0.48$ V relative to Ag/AgCl). The reduced electron carrier diffuses to release an electron to the platinum electrode, whereas the resultant porphyrin radical cation ($+1.10$ V relative to Ag/AgCl) captures an electron from the gold electrode, generating the cathodic current flow. There is, however, a competitive deactivation pathway in the excited porphyrin, via energy transfer quenching by the gold electrode, judging from the extremely short fluorescence lifetimes of the porphyrins (ca 10–40 ps) on the gold surface compared with those (ca 1–10 ns) on quartz or semiconductor surfaces [347–351]. Electronic coupling between the porphyrin and

the electrode would decrease as the number of methylene spacers was increased, leading to the less quenching of the excited porphyrin by the electrode via energy transfer through the spacer [352–356]. The rate of electron transfer from the gold electrode to the resulting porphyrin radical cation should, on the other hand, decrease with increasing spacer length. Thus, the offset effect of suppression of quenching by the gold electrode and reduced electron-transfer between the porphyrin and the electrode with increasing methylene spacer length is responsible for the nonlinear dependence of the quantum yield on the spacer length (*vide supra*). These results clearly show that optimization of each process is vital to achieving highly efficient sequential electron transfer by organized molecular systems used to mimic vectorial electron flow in photosynthesis.

The surface plasmon resonance technique has been applied to the characterization of the monolayer thickness of a self-assembled monolayer and to measurement of protein interactions with a self-assembled monolayer on the metal surface [357, 358]. Surface plasmon excitation has also been used as an effective excitation source to cause photoinduced electron transfer from the singlet excited state of the porphyrin in a self-assembled monolayer to electron carriers such as methyl viologen and O_2 in the electrolyte solution, leading to photocurrent generation [309, 327, 328, 336]. The surface plasmon was generated with p-polarized 632.8 nm light at an incident angle of 73° on a porphyrin (**19**)-modified gold surface of BK-7 right-angle prism by an attenuated total reflection method and by use of a Kretschmann–Raether configuration as shown in Scheme 20 [327, 328, 336].

The photoelectrochemical measurements were conducted in an oxygen-saturated 0.1 M aqueous solution of Na_2SO_4 using the **19**-modified gold working electrode, a platinum counter electrode, and an Ag/AgCl reference electrode [328]. The intensity of the cathodic photocurrent under the surface plasmon excitation is enhanced by a factor of ca 6 compared with direct photoirradiation [325, 338]. Such an enhancement of the photocurrent indicates that it is produced via the generation of surface plasmon and excitation of the porphyrin immobilized on the gold surface. These

Scheme 20.

results demonstrate that the surface plasmon resonance can be used to develop molecule-based photonic materials.

8.4.4 Self-assembled Monolayers of Porphyrin-containing Dyads

The importance and complexity of electron-transfer reactions in photosynthesis have inspired many synthetic chemists to design and prepare donor–acceptor linked systems that mimic the highly efficient multistep electron-transfer process [17, 334]. Because porphyrins and metalloporphyrins are essential components in photosynthetic electron transfer, they have been frequently employed in donor–acceptor linked molecules [17, 334]. Some covalently linked porphyrin-containing arrays, e.g. triads, tetrads, and pentads, produce a long-lived, charge-separated state with a high quantum yield, demonstrating that a sequential electron transfer is a pivotal strategy for the construction of artificial photosynthetic systems [17, 334]. Efficient conversion of light to photocurrents or chemical energies via the charge-separated state has, however, often been hampered by the poor unidirectional electron flow in covalently linked molecules incorporated into artificial membranes such as lipid bilayers and Langmuir–Blodgett membranes and/or organized at electrodes [258, 259, 261–265, 268, 271, 294, 295].

The spherical shape of buckminsterfullerene (C_{60}) containing a large number of π -electrons makes this carbon allotrope an ideal component for construction of efficient electron-transfer systems. Recent advances in synthetic methodology have made it possible to link C_{60} with porphyrins [17, 323, 334]. The first porphyrin–fullerene dyad (**20**) in a self-assembled monolayer was reported in 1996 [309, 318, 332]. Because sulfides are relatively stable compared with thiols and disulfides, a methylthio group is attached to the end of a porphyrin ring whereas the opposite end is a C_{60} moiety in **20**. The structures of the self-assembled monolayer formed on a gold electrode were studied by spectroscopic methods including X-ray photoelectron spectroscopy, ultraviolet–visible spectroscopic ellipsometry, ultraviolet–visible absorption spectroscopy, and Fourier transform infrared spectroscopy, as well as electrochemical methods [309, 318, 332]. The experimental data revealed that the porphyrin- C_{60} molecules were tilted and nearly parallel to the gold surface, leading to the formation of loosely packed structures ($\Gamma = 1.6\text{--}3.7 \times 10^{-11}$ mol cm $^{-2}$). Photoelectrochemical measurements were conducted in an argon-saturated aqueous solution of Na_2SO_4 , containing methyl viologen as an electron carrier, and using the modified gold electrode as a working electrode and a platinum counter electrode, as shown in Scheme 21 [309, 318, 332].

Under short-circuit conditions the cathodic photocurrent was observed for the photoelectrochemical cell; the quantum yield was ca 0.5 % [309, 318, 332]. The photocurrent intensity in the free-base porphyrin- C_{60} system was enhanced fivefold compared with that in the corresponding free-base porphyrin monomer system. Such enhancement of the photocurrent demonstrates that C_{60} acts as an effective mediator in a sequential electron-transfer process. The photocurrent intensity in the free-base porphyrin- C_{60} cell was ca one order of magnitude larger than that in the zinc porphyrin- C_{60} cell [309, 318, 332]. Two different electron-transport mecha-

Scheme 21.

nisms were proposed for photocurrent generation in self-assembled monolayers of porphyrin-C₆₀ systems—ion-pair formation for the zinc porphyrin-C₆₀ cell and exciplex formation for the free-base porphyrin-C₆₀ cell. The shorter lifetime in the charge-separated state of the former leads to a poor generation of the photocurrent, whereas the longer lifetime in the exciplex of the latter results in a pronounced increase of the photocurrent [309, 318, 332].

The dyad **21** consisting of a porphyrin linked to a thiol-appended benzoquinone as an acceptor was also prepared to construct a self-assembled monolayer system [310, 320]. The amount of **21** adsorbed, (Γ), was evaluated as 6.2×10^{-11} mol cm⁻² (270 Å² molecule⁻¹) from the amount of charge of the cyclic voltammogram. This occupied area of **21** doesn't agree with that expected for orientation of the porphyrin ring vertical to the electrode (90 Å² molecule⁻¹), indicating the rather poor packing of the molecule at the gold electrode. Photoelectrochemical measurements were performed in a nitrogen-saturated aqueous solution of Na₂SO₄ (pH 4.5), containing 50 mM EDTA as electron donor and 5 mM methyl viologen as electron acceptor, and using the modified gold working electrode, a platinum wire counter electrode, and an Ag/AgCl reference electrode as shown in Scheme 22.

Anodic and cathodic photocurrents were observed when the applied potential was more positive and negative than +200 mV which corresponds to the first reduction potential of the quinone moiety in the monolayer, respectively [359]. The potential dependence of the photocurrents as a function of pH in the electrolyte solution correlates well with the shift of the redox potential of the quinone as a function of pH [359]. When the applied potential is more positive than the redox potential of the quinone, photoinduced electron transfer occurs from the singlet excited state of the porphyrin to the gold electrode through the quinone, followed by a hole shift from the resultant porphyrin radical cation to EDTA, leading to the generation of anodic electron flow [359]. On the other hand, when the applied potential is more negative than the redox potential of the quinone moiety, photoinduced electron transfer takes place from the singlet excited state of the porphyrin

MV^{2+} : methylviologen; EDTA: ethylenediaminetetraacetic acid

Scheme 22.

to the methyl viologen, followed by a successive hole shift from the porphyrin radical cation to the gold electrode through the quinone moiety, producing the anodic electron flow [359].

Ferrocene acting as an efficient electron donor has also been linked with a porphyrin ring to construct the highly ordered structure of self-assembled monolayers of ferrocene-porphyrin dyad with an alkanethiol tail **22–24**, as shown in Scheme 23 [319, 329, 331].

The amounts of **22–24** adsorbed were estimated as $2.3 \times 10^{-10} \text{ mol cm}^{-2}$ ($71 \text{ \AA}^2 \text{ molecule}^{-1}$) for all the monolayers of **22–24** from the amount of charge in anodic peaks of the ferrocene moieties. The occupied area is close to that expected for ori-

Scheme 23.

entation of the porphyrin ring perpendicular to the electrode ($50 \text{ \AA}^2 \text{ molecule}^{-1}$) rather than that for vertical orientation ($250 \text{ \AA}^2 \text{ molecule}^{-1}$). Angle-resolved X-ray photoelectron spectroscopic studies on the monolayer of **23** confirmed that alkyl chains both between the porphyrin and the ferrocene and between the ferrocene and the thiol group were aligned with a tilt angle of 30° to the gold surface, with perpendicular orientation of the porphyrin plane [329]. The cathodic photocurrent was observed when the gold electrode modified with monolayers of **22–24** was irradiated with monochromatic light of 430 nm at an applied potential of -200 mV in a 0.1 M aqueous NaClO_4 solution containing 5 mM methyl viologen as an acceptor [331]. Quantum yields based on the absorbed photons were determined as 4.0, 11, and 12 % for photoelectrochemical cells of monolayers of **22**, **23** and **24**, respectively [331]. The photocurrent is generated via photoinduced electron transfer from the singlet excited state of the porphyrin to methyl viologen, then by successive hole transfer from the porphyrin to the gold electrode through the ferrocene moiety (Scheme 23) [331]. Photocurrent generation is limited by the efficiency of intermolecular electron-transfer quenching of the singlet excited state of the porphyrin by methyl viologen in competition with facile energy transfer quenching by the gold electrode, as described for the **18** monolayer system (*vide supra*). In addition, strong aggregation of the porphyrins without bulky substituents around the porphyrin moiety (**22–24**) in the monolayer might accelerate the non-radiative decay of the singlet excited state of the porphyrin. The flexible methylene spacer between the porphyrin and the ferrocene moieties does not enable comparison of the photo-dynamics in solutions with those in the monolayer on the gold surface; this is in sharp contrast with photoelectrochemical cells of the monolayers prepared from porphyrin- C_{60} dyad [309, 318, 332] and triad systems (*vide infra*) [333, 334, 339].

8.4.5 Self-assembled Monolayers of Porphyrin-containing Triads

A highly ordered self-assembled monolayer system of porphyrin-containing dyads has been extended to accommodate porphyrin-containing triads (**25** and **26**) [333, 334, 339]. The alkanethiol-attached triads **25** and **26** involve a linear array of ferrocene (Fc), porphyrin (P), and C_{60} as shown in Scheme 24. The energy gradient of each redox state in the triad is in the order: $\text{Fc}-^1\text{P}^*-\text{C}_{60} > \text{Fc}-\text{P}^{+\bullet}-\text{C}_{60}^{\bullet-} > \text{Fc}^+-\text{P}-\text{C}_{60}^{\bullet-}$. This makes it possible to achieve sequential electron transfer within the triad. The use of C_{60} as an electron acceptor in the triad has enabled the attainment of a long lifetime of the charge separated state and high quantum efficiency, as a consequence of the small reorganization energy of C_{60} [323, 334, 360–373]. Alkanethiols with long methylene chains ($n \geq 10$) are known to form densely packed self-assembled monolayers at a gold surface by use of the S–Au linkage [249, 342]. Thus, when a thiol group with a long alkyl chain is introduced at the end of donor–acceptor linked molecules, it would be arranged unidirectionally at the end of the gold electrodes, leading to formation of a uniform self-assembled monolayer with a thickness of ca 50 \AA (Scheme 24).

The fluorescence lifetime measurements of **25** and **26** in solution suggest that the quenching of the singlet excited porphyrin by the attached C_{60} is a major deactiva-

Scheme 24.

tion pathway in both triads [339]. The time-resolved transient spectra of the triads in different solvents revealed that initial photoinduced electron transfer or partial charge-transfer from $^1\text{P}^*$ to C_{60} occurred in the triads, followed by rapid charge shift from the ferrocene to P^{*+} to produce $\text{Fc}^+-\text{P}-\text{C}_{60}^{*-}$ [369]. The zinc complex affords a lifetime of 40 ns and 15.6 μs in benzene and DMF, respectively [369]. The overall quantum yield for formation of $\text{Fc}^+-\text{P}-\text{C}_{60}^{*-}$ depends on the solvent used. The quantum yield of the zinc complex is 65 % in benzonitrile, based on the absorption of both the porphyrin and C_{60} [369]. Given the relative absorption ratio of the porphyrin and the C_{60} , the quantum yield relative to $^1\text{ZnP}^*$ exceeds 80 %. The amount of **25** adsorbed at the gold electrode was estimated as $1.9 \times 10^{-10} \text{ mol cm}^{-2}$ ($= 86 \text{ \AA}^2 \text{ molecule}^{-1}$), which is comparable with those for well-ordered self-assembled monolayers of porphyrins [319, 325, 331, 338] and C_{60} [374–376] at gold electrodes. This indicates that the triad molecules are well-packed with nearly perpendicular orientation to the gold surface.

Photoelectrochemical experiments using the triad-modified gold electrode, a platinum wire, and an Ag/AgCl electrode were conducted in the presence of electron carriers such as oxygen and/or methyl viologen [333, 334, 339]. The cathodic photocurrent was detected under irradiation of the modified gold electrode with monochromatic light of 438.5 nm. Increasing cathodic photocurrent was observed with increasing negative bias on the gold electrode. This indicates that the direction of the electron flow is from the gold electrode to the counter electrode through the electrolyte. When the applied potential was more negative than +500 mV, which corresponds to the oxidation potential of the ferrocene, the photocurrent intensity increased drastically. Thus, the photocurrent efficiency is controlled by the rate of electron-transfer between the gold electrode and the ferrocene [319, 331]. The action spectra of the cells agree with the absorption spectra of **25** and **26** on the gold electrode. Such agreement indicates clearly that the porphyrin is a major photoactive species in photocurrent generation. The quantum yields for photoelectrochemical cells of **25** and **26** under the optimum conditions using an oxygen-

saturated solution in the presence of methyl viologen were found to be 25 % and 20 %, respectively. This is the highest value (25 %) among donor–acceptor linked molecules on monolayer-modified metal electrodes and in artificial membranes [258, 259, 268, 271, 294, 295, 309, 310, 318, 319, 325, 331, 332, 377].

The high quantum yield may be achieved via photoinduced electron transfer from the singlet excited state of the porphyrin to the C_{60} , then hole-shift from the resulting porphyrin radical cation to the ferrocene to produce the charge-separated state, $Fc^+-P-C_{60}^{\bullet-}$ in the monolayer (Scheme 24). The fast electron transfer to C_{60} , because of the small reorganization energy can compete well with deactivation as a result of the gold electrode [325, 338]. Electron carriers such as oxygen ($E^\circ_{red} = -0.48$ V for $O_2/O_2^{\bullet-}$) [378] and/or methyl viologen ($E^\circ_{red} = -0.62$ V for $MV^{+2}/MV^{\bullet+}$) are reduced by the $C_{60}^{\bullet-}$ moiety of $Fc^+-P-C_{60}^{\bullet-}$ to produce the radical anions which eventually give an electron to the counter electrode. The electron-transfer rate from the gold electrode to Fc^+ in $Fc^+-P-C_{60}^{\bullet-}$ is, on the other hand, affected by the potential applied to the gold electrode. Thus the rate of electron-transfer from the gold electrode to Fc^+ increases as the applied potential is reduced, leading to an increase in the photocurrent.

8.5 Summary

This review has focused on recent advances in the electron-transfer chemistry of porphyrins and metalloporphyrins, which is relevant to their biological role. Electron-transfer reactions of porphyrins and metalloporphyrins have been studied for long time and they are now relatively well understood on the basis of fundamental redox properties such as reorganization energies and the one-electron redox potentials in the light of the Marcus theory of electron transfer [1]. However, reaction mechanisms involving reactive intermediates such as high-valent metalloporphyrins produced in electron-transfer reactions of metalloporphyrins have remained incompletely understood, as discussed in this review. Axial coordination sites available in metalloporphyrins play an essential role in the construction of useful catalytic systems for biomimetic reactions and energy conversion, because simple combination of outer-sphere electron-transfer reactions would not increase overall electron-transfer rates. Strong inner-sphere interaction between substrates and metalloporphyrins results in the formation of a variety of substrate-bound intermediates; in particular new types of bimetallic active oxygen porphyrin complexes acting as reactive intermediates during the four-electron reduction of oxygen have been explored rapidly. Recent advances in self-assembled monolayer systems of porphyrins and metalloporphyrins have provided a promising means of developing biomimetic electron-transfer systems (in which highly ordered, well-designed architectures act as efficient catalysts) and organic solar cells. In each the search for new and better catalytic systems involving porphyrins and metalloporphyrins continues to be guided by beautifully constructed natural enzymatic systems.

Acknowledgment

The authors are deeply indebted to the work of all collaborators and coworkers whose names are listed in the references of this chapter (in particular, Prof. K. M. Kadish, Prof. Y. Watanabe and Prof. Y. Sakata). S.F. acknowledges continuous support of his study on electron-transfer chemistry by a Grant-in-Aid from the Ministry of Education, Science, Culture and Sports, Japan.

9 ESR Spectroscopy of Inorganic and Organometallic Radicals

Wolfgang Kaim

9.1 Introduction: The Information Accessible from ESR

Electron spin resonance (ESR) or, more generally, electron paramagnetic resonance (EPR) [1], is a physical method of analysis which, although restricted to paramagnetic species, is a powerful tool not only for the identification of such systems but also for kinetic investigations and, above all, for the study of their electronic structures. Information can come from the often temperature-dependent line-widths of the ESR signals (which are related to mobility and relaxation behavior), from the g factors (the equivalents of NMR 'chemical shifts'), from electron–nuclear hyperfine coupling (which might require electron–nuclear double resonance, ENDOR, as a more sophisticated method of analysis), and from zero-field splitting parameters, D , or exchange coupling values, J , for two-spin (triplet) or multi-spin systems.

It is assumed that the interested reader of this chapter has a basic knowledge of the theory and instrumentation associated with this particular variety of magnetic resonance, including perhaps a general introduction to the field of organic radicals. In keeping with the handbook character of this series, the following discussion will focus on special aspects of this method in inorganic and organometallic chemistry with emphasis on practical guidelines and references for the experimentalist, as suggested by own experience and illustrated by selected recent examples; a complementary excellent monograph on radical processes specifically in transition metal chemistry has recently appeared [2].

9.2 Inorganic and Organometallic Radicals: Definition, Generation and Peculiarities

The ESR spectroscopy of inorganic and organometallic systems with main group or transition element [2, 3] paramagnetic centers is distinguished from the study of organic radicals [4] by this method:

- 1) by the large number of isotopes available from the periodic table for electron–nuclear hyperfine interaction [5];
- 2) by the large spin–orbit coupling effects from the heavier elements (which affect both line-widths and g factors) [6];
- 3) by the possible use of s, p, d or f orbitals for the primary accommodation of spin; and
- 4) by possible occurrence of spin-delocalized spatial arrangements ('clusters') like, e.g., near-octahedral $[\text{B}_6\text{X}_6]^{*-}$ [7], which are quite different from the familiar planar π systems in organic radical compounds such as the formally analogous ions $[\text{C}_6\text{X}_6]^{*-}$ (X = halogen) [8].

Although inorganic or organometallic radical species may well consist of a single paramagnetic center with at least one unpaired s, p, d or f electron, there are also oligonuclear compounds with the ESR-detectable spin distributed over more than one 'inorganic' atom. Such phenomena are quite familiar in the field of oligomers (e.g. the 'platinum blues' $[\text{Pt}^{2-x}\text{L}_n]_4$) or paramagnetic clusters of transition metals such as $(\text{CoCp})_3(\mu_3\text{-CPh})_2$ [9]; they also occur, however, in the area of main-group elements as exemplified by ESR-characterized species such as $[\text{R}_2\text{Al-AlR}]^*$ [10], $[\text{R}_4\text{Ga}_4]^{*-}$ [11], $[\text{B}_6\text{X}_6]^{*-}$ [7], or $[\text{B}_9\text{X}_9]^{*-}$ [12] (R = alkyl, X = halogen), all with Group 13 element-centered spins.

In the context of inorganic and organometallic chemistry the term 'radical' needs a qualifying statement. Whereas paramagnetic main-group element compounds and most paramagnetic d block organometallic complexes with significant covalent bonding are usually referred to as radicals, the classical, i.e. non-organometallic transition metal coordination compounds [2, 3] e.g. of copper(II) or manganese(II) are usually not labeled correspondingly. Thus, the compounds $(\text{RX})\text{Mn}(\text{CO})_2(\text{C}_5\text{R}'_5)$ have been regarded as 'radical' species [13] although the spin resides mainly on the metal (low-spin Mn^{II} configuration **A** instead of the radical alternative **B** in Eq. 1), depending to some extent on the electronic effect of R [14]. In contrast, more conventional low-spin manganese(II) complexes such as $[(\text{ON})\text{Mn}(\text{CN})_5]^{2-}$ are not generally referred to as radicals [15]. The main reason for this practice lies in the often analogous reactivity (e.g. H-abstraction [16]) of organometallic 'radicals' in comparison with typical organic radicals such as $\cdot\text{CH}_3$.

X = NH, S, Se; R' = H, CH₃; R = aryl, alkyl

Paramagnetic coordination compounds where the spin resides *predominantly* on one or more of the organic (or inorganic) ligands are quite common, especially complexes of radical anions [17] such as *o*-semiquinones **1** or other negatively charged chelates such as tetrapyrrole macrocycles **2** [18].

(..... : potential coordinative bond)

Neutral radicals (e.g. NO[•] [19] or *N*-methylpyrazinium **3** [20]) and even cation radicals such as **4** [21] can also bind metal complex fragments to form ESR-detectable species.

Inorganic and organometallic radicals can be deliberately generated for ESR measurements in solution by irradiation (radiolysis, photolysis) [22] or by use of electrode processes ('ESR spectroelectrochemistry') [23] inside the microwave cavity of an ESR spectrometer ('in situ' or 'intra muros' generation), and they can occur as intermediates (transients) [2] or final 'escape' products of thermally or light-induced electron transfer reactions [24, 25]. The use of suitable oxidants or reductants for chemical radical generation in the organometallic field has been excellently reviewed by Connelly and Geiger [26].

The following discussion summarizes important criteria and parameters for the application of ESR in inorganic and organometallic chemistry, illustrated by selected examples.

9.3 Selected ESR Parameters

9.3.1 Concentration and Lifetime of Radicals

Many of the frequently invoked radicals in inorganic or organometallic chemistry, e.g. the thermally or photochemically generated species $\cdot\text{M}(\text{CO})_5$, $\text{M} = \text{Mn}$ or Re [27], are too short-lived to be observed in the necessary useful concentrations of about $c > 10^{-7} \text{ M}$ by conventional ESR methods under standard conditions. Although continuous wave (CW) ESR is a well-established detection method for kinetic techniques such as stopped or continuous flow [28], this method is limited to lifetimes of ca $\tau > 10^{-4} \text{ s}$ for the paramagnetic intermediates. To detect and study species which would be shorter-lived under standard conditions the following techniques have been developed; they are illustrated by examples involving an important elementary process in organometallic chemistry, viz. homolytic $\text{M}-\text{C}_{\text{sp}^3}$ bond dissociation.

Irradiation of immobilized species in matrices by use of electrons, UV-Vis, X- or γ -rays and direct observation of thus stabilized radicals under static conditions [22]

Many short-lived small inorganic radicals and unusual transition metal centers have been generated by photolysis or radiolysis methods in matrices [22]. (The matrix can be a glassy frozen solvent or a solid, e.g. zeolite or other oxide). This method is, however, also suitable for investigation of rather complex systems such as alkyl cobalamins and related ' B_{12} ' species [29, 30]. Irradiation with visible light is even sufficient to cleave the crucial $\text{Co}-\text{C}_{\text{alkyl}}$ bond in these macrocyclic compounds to yield Co^{II} products and the less persistent alkyl radical intermediates; both can be detected by ESR in low-temperature matrices (Eq. 2) [30].

CD_3OD

$[\text{Co}] = \text{cobalt corrin complex}$

Trapping of short-lived radical intermediates as generated by photolytic, thermal or chemical processes with the help of NO-containing 'spin traps' such as alkyl nitrones or nitroso compounds [31]

This popular approach, illustrated by Eq. 3 [32] for an organometallic example, must be carefully checked with respect to the question whether the resulting stable and thus ESR-observable species (e.g. a nitroxide radical complex) is perhaps just a product from a preformed 'charge-transfer' complex between the substrate and the spin trap.

$\text{N}^{\wedge}\text{N} = \alpha$ -diimine

$$a(^{14}\text{N}) = 1.58\text{ mT}$$

$$a(^{195}\text{Pt}) = 4.0\text{ mT}$$

Pulsed ESR methods

Pulsed ESR methods (FT-ESR) have been increasingly developed during the last decade for use in direct time-resolved studies [33] of transient species. Although this technique is excellently suited to the investigation of typical inorganic and organometallic reactivity such as the light-induced metal/ sp^3 -carbon bond homolysis (Eq. 4) [34], the corresponding metal-containing radical products such as $[(\text{N}^{\wedge}\text{N})\text{Re}(\text{CO})_3]^{\bullet}$ ($\text{N}^{\wedge}\text{N} = \alpha$ -diimine ligand) may not be directly detectable owing to unfavorable relaxation properties (cf. Section 9.3.2).

$\text{N}^{\wedge}\text{N} = 4,4'$ -dimethyl-2,2'-bipyridine

This organometallic radical product could, however, be detected by irradiation in glassy frozen matrices [34]. The alkyl radicals, as very short-lived metal-free products, could be observed and analyzed by FT-ESR with respect to CIDEP (chemically induced dynamic electron polarization) effects [34].

9.3.2 Line-width and Temperature

Whereas almost all organic radicals give rather narrow ESR signals in solution, with widths of individual hyperfine lines well below 1 Gauss (0.1 mT) [4], signals in the spectra of inorganic and organometallic radicals can be severely broadened, sometimes beyond ESR detectability even at very low temperatures. In the absence of special (e.g. dynamic) effects, this phenomenon is usually a result of strongly shortened relaxation times after excitation by microwave radiation. The enhanced relaxation of inorganic or organometallic radicals is generally favored by the presence of heavy atoms with their large spin-orbit coupling constants [6] and the numerous available states, often close-lying, involving contributions from s, p, d or f atomic orbitals of one or more of the 'inorganic' atoms. Di- and polynuclear radical

compounds (clusters) and high symmetry species (T_d , O_h) with degenerate spin-bearing orbitals can have particularly pronounced effects for the very same reason—close-lying excited states from which rapid relaxation to the ground state can occur.

To detect such radicals by ESR, low temperatures must be routinely employed, and even then otherwise (e.g. structurally or magnetically) well-characterized species can remain 'ESR-silent' at 77 K ($[B_6I_6]^{*-}$ [8], $[Fe(C_5H_5)_2]^+$ [35a], $[(bpy)_2Ru(\mu-OC(R)NNC(R)O)Ru(bpy)_2]^{3+}$ [35b]) or 4 K ($Re^{VI}S_4^{2-}$ [36a], $[(N^{\wedge}N)Pt^{III}R_2]^+$ ($N^{\wedge}N = \alpha$ -diimine) [36b], $[In_4R_4]^{*-}$ [11], $[(bpy)_2Os(\mu-OC(R)NNC(R)O)Os(bpy)_2]^{3+}$ [35c]). Obviously, such effects can occur with main-group element-, transition metal- and even ligand-centered spins [37]. NMR of paramagnetic substances can then sometimes be employed as a complementary technique [38]; lowering the symmetry, e.g. by coordination of metal complex fragments to ReS_4^{2-} is another alternative [36a, c].

In contrast, disappearance of ESR signals when the temperature is *lowered* is usually a sign of intermolecular association, e.g. to form a spin-spin coupled dimer with a singlet ground state. Triplet states might, however, then be thermally accessible, or the triplet may even become the ground state of the system (cf. Section 9.3.5).

Decreasing ESR line-width and improved spectral resolution at higher temperatures is usually a sign of enhanced mobility in solution resulting in better averaged anisotropic contributions from hyperfine and g tensors; ESR spectroscopy at X-band frequency is distinguished by a characteristic time-scale of ca 10^{-8} s (cf. Section 9.3.6). Inorganic and organometallic radicals are often severely affected by selective 'anisotropic line-broadening' [4] because of large A or g anisotropy and/or slow tumbling (long rotational correlation times) in solution; the higher masses of inorganic elements and the resulting larger moments of inertia often contribute to increased ESR line-widths as exemplified by the series of compounds $[R_2M-MR]^{\bullet}$, $M = Al, Ga$ [10, 39b, c], or **6** [39a].

6

9.3.3 The g Factor

According to the ESR resonance condition, $h\nu_r = g\beta H_r$, the g value is the proportionality factor between the resonance frequency ν_r and the resonance field H_r .

The g factor thus has the same role as the absolute chemical shift in NMR spectroscopy. In a purely electron spin-governed ('spin only') situation, the g factor would have the value $g_e = 2.0023$ as calculated and measured for the free electron [1], although even small contributions from excited states with non-zero orbital angular momentum through spin-orbit coupling will affect this value, especially if nuclei with high spin-orbit coupling constants [6] contribute significantly. Thus easily detectable deviations, Δg , of the isotropic g factor from the free electron value are observed for inorganic and organometallic radicals, even if the spin is still largely (>95 %) ligand-centered; a deviation such as $g_{iso} = 2.0093$ for the Cu^{I} -semiquinone complex **7** [40] translates to $\Delta g = 0.0070$, a relative shift of about 3500 ppm.

For metal-centered spin, this deviation can be substantially higher. Thus, for the Cu^{II} /catecholate compound **8** $g_{iso} = 2.113$, which corresponds to a shift of ca 5.5×10^4 ppm [40].

The sign of the deviation is indicative of the frontier orbital situation—according to Stone's approximation (Eq. 5) [41]:

$$g = g_e - \frac{2}{3} \sum_i \sum_n \sum_{kj} \frac{\langle \psi_0 | \xi_k \mathbf{L}_{ik} \delta_k | \psi_n \rangle \langle \psi_n | \mathbf{L}_{ij} \delta_j | \psi_0 \rangle}{E_n - E_0} = g_e + \Delta g \quad (5)$$

ξ : spin orbit coupling constant

\mathbf{L} : angular momentum operator

E_0 : energy of singly occupied molecular orbital (SOMO)

Scheme 1.

A deviation to higher values than g_e is to be expected if $E_0 > E_n$, i.e. if the highest lying fully occupied MO lies closer to the SOMO than the lowest empty MO. Such is the case for almost all low-spin d^5 and d^9 systems [2] (cf. **8**) or for the radical complex **7** [40].

The other alternative, $E_0 < E_n$, with the lowest empty MO lying closer to the SOMO than the highest occupied MO leads to lower g factors than g_e as is typical for d^1 systems [2] and, e.g., for **9** [42].

**9**

The effect of increasing spin-orbit coupling constants on the deviation Δg of g from g_e is evident, e.g., for Group-6 carbonylmethyl(0) complexes $[(OC)_nM](A^{\bullet-})$ of heterocyclic anion radical ligands where the greatest such deviation—positive or negative—is invariably observed for the tungsten homolog [43]. Such correlations are, however, only valid for paramagnetic systems with the inorganic nuclei in chemically comparable environments. An example where the $4d^5$ compound has less g anisotropy g_1-g_3 than a $3d^5$ analog is described below [44a].

In efforts to mimic the function of heterobimetallic hydrogenases and provide potential molecular catalysts for fuel cell technology the Fe,Ru-heterobimetallic hydride complex $[Cp^*RuH(dppf)]$, $dppf = 1,1'$ -bis(diphenylphosphino)ferrocene, has been reported [44b] to catalyze the elementary reaction $H_2 \rightarrow 2H^+ + 2e^-$. It was suggested [44b] that the crucial oxidation involves the ruthenium center and not

Figure 1. Comparison of iron and ruthenium oxidation in 1,1'-bis(diphenylphosphino)ferrocene-ruthenium(II) complexes (ESR spectra [44a] from electrolytically oxidized solutions of precursors [44b, c] in THF at 4 K): Oxidation of $[\text{Cp}^*\text{RuH}(\text{dppf})]$, $\text{dppf} = 1,1'$ -bis(diphenylphosphino)ferrocene, and $[(\text{Cym})\text{RuCl}(\text{dppf})](\text{PF}_6)$, $\text{Cym} = p$ -cymene, occurs at ruthenium for the former compound but yields a ferrocenium species for the latter.

the iron of the ferrocene ligand. Figure 1 illustrates the EPR evidence that there is a viable alternative $\text{Fe}^{\text{II}}\text{Ru}^{\text{III}}$ rather than $\text{Fe}^{\text{III}}\text{Ru}^{\text{II}}$ by describing a similar species, the recently structurally characterized [44c] complex $[(\text{Cym})\text{RuCl}(\text{dppf})](\text{PF}_6)$ with a neutral arene (p -cymene) instead of a cyclopentadienide and a chloride instead of a hydride co-ligand at ruthenium.

Both complexes are reversibly oxidized but the resulting ESR signals in glassy frozen solution differ significantly (Figure 1). Whereas the organometallic low-symmetry low-spin ruthenium(III) center in $[\text{Cp}^*\text{RuH}(\text{dppf})]^+$ has relatively small g anisotropy with $g_1 = 2.187$, $g_2 = 2.088$ and $g_3 = 1.991$ ($g_1 - g_3 = 0.196$), the ferrocenium systems with their special symmetry and d orbital splitting are typically distinguished by broad ESR signals, often observable only at 4 K [35a], with large g anisotropy. Complex $[(\text{Cym})\text{RuCl}(\text{dppf})]^{2+}$ is thus properly formulated as a ferrocenium/ Ru^{II} system with $g_1 = 3.612$ and $g_{2,3} = 1.765$ ($g_1 - g_3 = 1.847$) [44a].

In just the same way as the hyperfine coupling, the g factor has tensor structure [1] which can be studied in detail by examining single crystals of radicals [3b, 45]. In many instances, however, the intermediate character of such species allows for investigation in the powder state only or in glassy frozen solutions which then yield up to three separated g factor components, according to the symmetry of the SOMO [3]. The splitting of these g components, including the total g anisotropy, symmetry, and positions of the individual components is valuable ESR information

for the identification of the SOMO as has long been known for classical paramagnetic transition metal complexes, e.g. in metal d [3] or f [46] orbital analysis. The influence of increasing spin-orbit coupling constants from heavier elements on the g anisotropy $g_1 - g_3$ is nicely illustrated by the series of chalcogen-based 19-electron triatomic bent radicals [47a] $\text{O}_3^{\cdot-}$ ($g_1 - g_3 = 0.0161$), $\text{SeO}_2^{\cdot-}$ ($g_1 - g_3 = 0.0342$), and the new $\text{TeS}_2^{\cdot-}$ ($g_1 - g_3 = 0.0719$) [47b].

Large line-widths, sometimes in conjunction with insufficiently resolved hyperfine structure, can preclude the determination of individual g factor components close to $g = 2$ under conventional ESR conditions (X band, 9.5 GHz, 330 mT). As in NMR spectroscopy, an increase in the field and frequency is then appropriate via the Q band (35 GHz) to the W band (95 GHz) or even higher frequencies and magnetic fields [48]. An application of such high-field ESR for the inorganic radical **10** with sizeable metal participation has been reported [49a].

10

The rather large $^{63,65}\text{Cu}$ hyperfine coupling of about 1.7 mT [49b] from two copper nuclei in the stable, crystalline [49c] blue complex **10** has raised the question whether these centers are still correctly described as Cu^{I} or whether they have some Cu^{II} character. Unfortunately, the extensive hyperfine coupling [49b] from two $^{63,65}\text{Cu}$, two ^{14}N and four ^{31}P nuclei caused complete broadening of the X band ESR signal in glassy frozen solution. Increasing the frequency by a factor of 25 to 245 GHz, however, revealed three well-separated g components [49a] the values of which ruled out any significant contribution from copper(II) states.

9.3.4 Electron–Nuclear Hyperfine Coupling

In principle, ESR hyperfine coupling between the unpaired electron and the various nuclei (isotopes) of the radical species is the most informative data from ESR, both

for identification of the species and for elucidation of the electronic structure. Although, ideally, all nuclei with non-zero nuclear spins couple to a certain extent with the unpaired electron in a molecule and thus reveal the nature of the singly occupied molecular orbital (SOMO), there might be severe limitations affecting this kind of information.

- 1) To begin with, the intrinsic line-width might be too large for the resolution of the hyperfine structure for the reasons given in Section 9.3.2 or because of dynamic phenomena (e.g. electron hopping [42, 50]; Section 9.3.6). Graphical analysis of only partially resolved ESR hyperfine structure may be facilitated by mathematical derivatization, e.g. of the usually recorded first derivative to the second derivative spectrum [45] (whereby mere turning points become maxima or minima), or by computer-assisted simulation (spectrum synthesis) with estimated line-widths and line-shapes. Computer simulation is not only necessary when very many lines (see point 4, below) from several different coupling nuclei overlap, it may also be appropriate when large line-widths and unusual nuclear spin situations combine to yield ESR spectra of unfamiliar appearance. One such example are the various manifestations of 'two-line' patterns as observed [51, 86], e.g., for the dominant coupling of one rhenium atom with the unpaired electron. It arises through the cancellation (by overlap) of the innermost lines of the sextet expected for the hyperfine interaction with $^{185,187}\text{Re}$ (100 % total natural abundance, $I = 5/2$ and very similar nuclear magnetic moments for both isotopes). Increasing the line-width by lowering the temperature illustrates this effect experimentally (Figure 2).
- 2) Secondly, the isotopic properties [5] of the nuclei of interest might not be suitable because of absent nuclear spin ($I = 0$; e.g. ^{12}C , ^{18}O , ^{32}S , ^{56}Fe) or the low natural abundance of isotopes with $I \neq 0$ (^{13}C : 1.1 %, $I = 1/2$; ^{17}O : 0.038 %, $I = 5/2$; ^{33}S : 0.75 %, $I = 3/2$; ^{57}Fe : 2.15 %, $I = 1/2$). Manipulation of the natural isotopic composition, e.g. by selective enrichment, is then appropriate. The enrichment may involve metal isotopes such as ^{95}Mo (15.9 %, $I = 5/2$) or ^{61}Ni (1.1 %, $I = 3/2$) in biological probes [52] (where this method might even analytically establish the presence of corresponding trace elements), or, e.g., ^{13}C nuclei in radical ligands, as illustrated by compound **11** with its very different participation of axial and equatorial carbonyl ligands in the spin distribution [53, 64b].

**11**

$$a(^{13}\text{C}_{\text{eq}}) < 0.01 \text{ mT}$$

$$a(^{13}\text{C}_{\text{ax}}) = 0.601 \text{ mT}$$

Figure 2. Temperature dependence of the ESR spectrum of tetracarbonyl(phenanthrenesemiquinone)rhenium(I) complex $[(pq)Re(CO)_4]^+$ in toluene (cf. K. A. M. Creber, T. I. Ho, C. Depew, D. Weir, J. K. S. Wan, *Can. J. Chem.* **1982**, 60, 1504). The $^{185,187}Re$ sextet hyperfine coupling dominates, yet increasing line-width at lower temperatures causes significant distortion of the sextet coupling as a result of overlapping of the innermost lines.

Similarly, de-enrichment or isotope exchange may also improve the detectability of ESR hyperfine structure and permit the assignment of coupling constants. Isotopically pure ^{65}Cu instead of the naturally occurring $^{63,65}Cu$ isotope mixture has been used in bioinorganic studies and H/D exchange (2D : $I = 1$, $\mu_H/\mu_D = 6.5$) is frequently employed in, e.g., transition metal hydride chemistry [54].

3) A further limitation even in otherwise favorable circumstances is the very low

nuclear magnetic moment μ of certain isotopes such as ^{101}Rh (100 %, $I = 1/2$) [55a] or $^{191,193}\text{Ir}$ (100 %, $I = 3/2$) which then results in small and frequently undetectable hyperfine coupling, even with high spin density on the nucleus. As an example, distinctly increased g anisotropy and relaxation rates are observed for electrogenerated $\text{M}^{\text{I}}/\text{M}^{\text{II}}$ mixed-valent systems $[(\text{Cp}^*\text{M}(\mu\text{-dip})\text{MCp}^*)^+]^+$ ($\text{M} = \text{Rh}, \text{Ir}$; dip = 2,5-diiminopyrazine ligand) in comparison with the related radicals $[\text{Cp}^*\text{ClM}(\mu\text{-dip})\text{MClCp}^*]^{\cdot+}$; hyperfine information (which would settle the question of localized or delocalized valences) could not, however, be obtained because of the unfavorable isotopic situation [55b, c].

dip

Conversely, a fairly large inorganic isotope coupling constant such as 1.8 mT for $^{69,71}\text{Ga}$ may suggest an unusual oxidation state (here mononuclear Ga^{II}) [56] in a compound **12** where in fact a regular diamagnetic Ga^{III} center binds one radical anion and one dianionic α -diimine ligand [57].

**12**

In a similar manner, the platinum(I) oxidation state has sometimes been invoked [58] in complexes $[(\text{N}^{\wedge}\text{N})\text{PtL}_n]^k$ ($\text{N}^{\wedge}\text{N} = \alpha$ -diimine ligand) because of large ^{195}Pt isotope coupling where in fact the Pt^{II} center is bound to a one-electron reduced $\text{N}^{\wedge}\text{N}$ ligand [36b, 59]. True Pt^{I} species with $5d^9$ configuration are quite rare and reactive and have very large coupling constants and g anisotropies [60].

- 4) The multiplicative connection in Eq. 6 for the total number of hyperfine lines can rapidly lead to so many overlapping individual lines that analysis from the ESR experiment alone becomes impossible and an unresolved, inhomogeneously broadened signal results.

$$N = \prod_i (2n_i I_i + 1) \quad (6)$$

N : number of hyperfine lines

n_i : number of equivalent nuclei in set i

I_i : nuclear spin of the isotopes in set i

Fortunately, many nuclei do not contribute to hyperfine splitting in any given radical because of absent nuclear spin, low magnetic moment, or marginal spin density; there are, however, exceptions. For instance, the symmetrical delocalization of spin over all boron and halogen atoms in the stable, near-octahedral cluster radical anion $B_6I_6^{\bullet-}$ [7] results in a total number of 25 606 theoretical lines involving the nuclei ^{10}B (19.8 %, $I = 3$), ^{11}B (80.2, $I = 3/2$), ^{127}I (100 %, $I = 5/2$), according to a statistical treatment for the seven isotopic combinations of the chemically symmetrical species $[^{10}B_n^{11}B_{6-n}^{127}I_6]^{\bullet-}$, $n = 0-6$. In such cases, or for low-symmetry systems with many *different* coupling constants [21b], use of the electron-nuclear double resonance (ENDOR) technique reduces the number of lines, because each coupling constant is represented by only two lines on the radiofrequency scale [61]. Because of the required saturation of the ESR transition and rather specific requirements for the relaxation rates [61], which are different for each nucleus, the ENDOR method is not always straightforward with inorganic or organometallic radicals in solution; examples are, however, known for main group element radicals such as **13** (^{10}B , ^{11}B , ^{27}Al heteronuclear ENDOR) [62] and transition metal containing species [21b, 31b, 63] such as **14** [63b].

**13****14**

Pulsed ENDOR methods have been developed to obtain maximum hyperfine information [33a, 55a].

The occurrence of hyperfine coupling for a particular isotope indicates non-zero spin density at that nucleus in accordance with the Fermi contact term (which includes the electron wave function evaluated at the nucleus) [1]. The analysis in terms of spin density then requires at least a comparison with the (calculated [5]) isotropic hyperfine splitting constant a_0 ; ideally, results from increasingly available open-shell quantum-chemical calculation procedures [64] are employed.

The hyperfine structure may also indicate, in a rather elementary way, the symmetry and thus intramolecular electron exchange situation of radicals. For instance,

organometallic mixed-valent species $(R_5C_5)(OC)_2Mn^{1.5}(\mu-L^-)Mn^{1.5}(CO)_2(C_5R_5)$, $L = RO^-$ or imidazolate (**15**), exhibit their delocalized ground state (involving rapid intramolecular electron exchange) through the coupling of one unpaired electron with two *equivalent* nuclei ^{55}Mn (100 %, $I = 5/2$) [65]. The resulting eleven lines are spaced with a coupling constant roughly one half of that for corresponding mononuclear species $(R_5C_5)(OC)_2Mn^{II}(L^-)$ [65]. In contrast, dinuclear $Mn^{III}Mn^{IV}$ model complexes for the oxygen-evolving manganese clusters in photosystem II clearly show 16 lines with an intensity distribution that indicates two different coupling constants for the two Mn centers, signifying slow intramolecular electron exchange and a localized mixed-valent situation [66].

**15**

Similar metal-metal spin delocalization could be established directly by ESR for dimolybdenum systems **16** [67] or $[(Tp^*)(X)ClMo(\mu-L)MoCl(X)(Tp^*)]^x$,

**16**

Tp^* = tris(pyrazolyl)borate derivative, L = bipyridine ($X = NO$) or bisphenolate ($X = O$) bridging ligands [68]. Because of the presence of only 25.5 % as hyperfine coupling-active nuclei *Mo (^{95}Mo with 15.9 % and ^{97}Mo with 9.6 %, both with $I = 5/2$), the delocalization is evident from the approximately halved hyperfine coupling constants (as compared with mononuclear Mo^I species) and from the relative ESR intensities of lines corresponding to molecules with $^*Mo-^*Mo$, $^*Mo-Mo$ and $Mo-Mo$ isotope combinations [67, 68].

9.3.5 Zero-field Splitting and Exchange Coupling

The presence of two spins in a triplet [70, 71] or biradical [72] species results in additional ESR features, viz. fine structure effects as a result of electron spin–electron spin interactions [69]. The phenomena observed and results derived therefrom are best discussed for simple examples, viz., the interaction of two equivalent centers in structurally well-characterized molecules.

A particularly simple situation exists in titanium(III) or vanadium(IV) dimers with d^1 configured centers. Titanium(III) dimers with sandwich structures have been studied in respect of ESR and magnetic effects of d^1 – d^1 interaction [70]. As an example, neutral and ionic titanacarborane dimers with Ti^{III} – Ti^{III} distances of ca 3.7 Å afforded well-resolved triplet ESR spectra [70], especially, with the support of a commercial ‘dual mode’ ESR cavity which, in the parallel polarization ESR mode, $B_2 \parallel B_1$, enhances the observability of otherwise forbidden $\Delta M_S = \pm 2$ transitions over the regular $\Delta M_S = \pm 1$ transitions. Analysis of both features provides zero-field splitting parameters D (axial) and E (rhombic), g factor components, and spin–spin distances which agree with the crystallographically determined features and permit a discussion of through-bond and through-space interaction [70].

Inspection of the half-field region, especially with the dual mode cavity, may reveal triplet ESR features and thus spin–spin interaction in coordination chemistry even when such effects are not necessarily expected. The tendency of inorganic and organometallic compounds to associate via coordinate or other bonds can be detected through corresponding triplet ESR signals, as illustrated by the crystallographically characterized copper(II) complex **8** [79] which seems to form a dimer with ESR half-field features on cooling in a frozen glassy solution of THF [79].

Weak coupling of organometallic biradicals such as the hydrogen-bridged dimer of $(\eta^7\text{-C}_7\text{H}_7)\text{V}(\eta^5\text{-C}_5\text{H}_4\text{COOH})$ can be detected in solution via simulation of ESR spectra [72]. Rather small exchange coupling constants $|J| < 1 \text{ cm}^{-1}$ may thus be established, providing a complementary technique to NMR and susceptibility measurements.

9.3.6 Dynamic Effects

In common with all spectroscopic methods, ESR is characterized by a certain ‘characteristic time-scale’ as determined by the typical energy involved in the transition. For ESR at X band frequency, this window lies between ca 10^{-7} and 10^{-10} s,

i.e. in the range of intermediate-to-slow molecular rotations and vibrations. The processes resulting in dynamic ESR effects might thus involve, e.g., conformational changes, as frequently encountered in the ESR spectroscopy of organic radicals [4]. Such structural changes also play an important role in inorganic and organometallic chemistry [73]; the changes in electron and atom location (i.e. coordination) are, however, more typical and will be illustrated here by examples.

The exchange of one unpaired electron between two or more equivalent or nearly equivalent sites can be monitored by ESR spectroscopy. A classical example is the 'hopping' of an added or charge transfer-generated electron between the three α -diimine chelate ligands of $[\text{Ru}(\text{bpy})_3]^{n+}$ (**9**) and related complexes.

Scheme 2

In contrast with the short-lived MLCT-excited states $^*[\text{Ru}(\text{bpy})_3]^{2+}$ [74], the electrogenerated $[\text{Ru}(\text{bpy})_3]^{+}$ can be conveniently studied by temperature-dependent ESR [42, 50a, b]. Analysis of the broad unresolved lines of this and related species reveals electron hopping between the three equivalent ligand sites with activation energies of approximately 10 kJ mol^{-1} . Similar slow vs. fast exchange phenomena were reported for the 'extended atom' [75] species **17** which contains an encapsulated Na^+ ion and mobile spins in the bpy-containing periphery.

Characteristically, more unsymmetrical analogs $[\text{Ru}(\text{L})(\text{bpy})_2]^{+}$ with one better accepting ligand L give much narrower, often resolved, ESR signal lines, because of the localization of spin on L [42].

For the remaining alternative $[\text{Ru}(\text{L})_2(\text{bpy})]^{+}$ in that series, e.g. with $\text{L} = 2,2'$ -azobispyridine (abpy), the hopping behavior between the two L sites was found

17

[50c] to depend characteristically on the stereochemistry of the complex which can exist in three different configurations [50c].

In contrast, the complex $[\text{Cu}^{\text{I}}(\text{N}^{\wedge}\text{N})_2]^{\bullet}$ gave no ESR signals for rapid electron hopping between the two $\text{N}^{\wedge}\text{N} = 2,9\text{-diphenyl-1,10-phenanthroline}$ ligands—probably as a result of the nearly orthogonal arrangement of the ligand π systems [77].

In special circumstances the metal and a ligand can compete for the spin in a paramagnetic complex. As this alternative involves oxidation-state changes, it is referred to as valence tautomerization or redox isomerization [78]. Such behavior is observed for *o*-semiquinone complexes of cobalt and manganese [78]; recently, a copper(I)-semiquinone–copper(II)-catecholate equilibrium system (7) of biochemical interest has been analyzed by temperature-dependent ESR [79].

An equilibrium such as (7) between two paramagnetic species with sufficiently different ESR signals can be analyzed quantitatively [79] by double integration, i.e. from the conventionally recorded first derivative signal to the zeroth derivative spectrum and then further to the first integrated form. The procedure requires a careful definition of the baseline, especially for broader spectra.

Changes in the coordination mode of paramagnetic complexes can sometimes be easily followed by ESR spectroscopy. For instance, the alternative binding (18, 19) of the Group-6 metal fragments $(\text{OC})_5\text{M}$ to either the N or the chalcogen atom of

reduced 2,1,3-benzochalcogenodiazoles can be evident from the symmetry of the ESR hyperfine splitting in the radical anion ligand [80].

An electron transfer-sensitive σ/π coordination alternative of substituted olefins to metal centers has been demonstrated [81] in the system $[(\text{NC})_2\text{C}=\text{C}(\text{CN})_2\text{W}(\text{CO})_5]^n$ (**20**) where the π complex with $n = 0$ (olefin coordination) changes reversibly to an ESR detectable σ complex (nitrile coordination) after one-electron reduction ($n = -1$). Even in the absence of a detailed spin population analysis the low symmetry of the anionic complex is evident from at least three distinctly different ^{14}N coupling constants in the ESR spectrum [81].

Examples of ESR-detected coordination changes do not have to involve organic radical ligands. For instance, the relatively slow changeover in a multimodal copper(II) catenate could be conveniently monitored by ESR spectroscopy [82].

The electrochemically triggered molecular rearrangement involves oxidation from a four-coordinate Cu^{I} to an intermediate four-coordinate Cu^{II} species which has a distinctly different ESR spectrum (higher g , lower $a(^{63,65}\text{Cu})$; measured in frozen solution) than the more stable five-coordinate Cu^{II} alternative. The latter is formed by fairly slow rotation of interlocking macrocyclic rings; it reverts to the four-coordinate arrangement on re-reduction [82].

In favorable circumstances, ESR spectroscopy is also capable of detecting coordination changes which might have otherwise gone unnoticed. As an example, the reduction of the complex **21** produces a well-resolved ESR spectrum which shows only two equivalent ^{31}P nuclei (100 %, $I = 1/2$) interacting with the unpaired electron [83]. Apparently, two triorganophosphane ligands are lost after the reduction because of the high electron density created at the d^6 -configured metal centers [83] (pentacoordination [84]).

9.3.7 ESR Information and Chemical Reactivity

ESR Spectroscopy is not only superbly suited to the analysis of metal centered [3], metal/ligand mixed [35b] or ligand centered [85] singly occupied molecular orbitals; in favorable circumstances some ESR parameters can even be directly correlated with chemical reactivity. Although such correlations are obvious if ESR-monitored metal oxidation-state changes are involved, even small but variable amounts, δ , of unpaired electron density transmitted from radical ligands to potentially reactive metal centers can cause significant reactivity variations which are mirrored by ESR data. As an example, the rhenium halide bond labilization in reduced complexes $[(\text{N}^{\wedge}\text{N})\text{Re}(\text{CO})_3\text{X}]^{\cdot-}$ (**22**; $\text{N}^{\wedge}\text{N} = \alpha$ -diimine ligand, $\text{X} = \text{halogen}$) correlates with the $^{185,187}\text{Re}$ (and, if detectable, ^{14}N) hyperfine splittings [86]. Both kinds of ESR data quantify the ligand-to-metal spin transfer δ at the ligand-metal interface in

such $18+\delta$ valence electron compounds [86–88]; this, in turn, determines the substitutional labilization of the axial and partially [51, 86] charge-accepting ligand.

A related interesting phenomenon is the electron reservoir behavior of coordination compounds [89]. For instance, compounds $[(A)(C_nR_n)M^kX]^+$ with acceptor-bound organometallic reaction centers can accommodate one first added electron in the acceptor ligand A before a second added electron combines with the stored one to effect a chemically productive two-electron process at the metal (Eq. 8) [90].

$M = \text{Rh}, \text{Ir}, k = +\text{III}, n = 5; M = \text{Os}, k = +\text{II}, n = 6; X = \text{halogen};$

$A = \text{acceptor, e.g. } \alpha\text{-diimine}$

In the synthetically attractive field of electron transfer catalysis (ETC) [2, 91], ESR data of radical intermediates can correlate with the variable efficiency of processes such as the ETC-catalyzed substitution (9) by substantiating the amount of ligand-to-metal electron transfer in the ground state [87].

requirement for ETC:

$E_{\text{red}} [(A)M(CO)_{n-1}(PR_3)]$

$< E_{\text{red}} [(A)M(CO)_n];$

$A = \text{pyridine derivative, } \alpha\text{-diimine}$

9.3.8 Concluding Remarks

The previous chapters and examples were meant to familiarize the reader with current conventional ESR methodology and remove any barriers to the application of this kind of spectroscopy in electron-transfer studies. Unavoidably, not all aspects of inorganic ESR could be treated properly; for instance, both the ESR spectroscopy of bioinorganic systems (e.g. heme species or iron–sulfur clusters) or materials chemistry (e.g. defect centers, radicals in zeolites) are vast and entirely independent research areas. Nevertheless, the molecular species presented here might serve as introductory examples to illustrate the versatility of this particular kind of magnetic resonance.

Acknowledgments

Support for the author's ESR research has been continuously provided by the Deutsche Forschungsgemeinschaft (DFG) and Volkswagenstiftung. In particular, support for the recent graduate college 'Magnetic Resonance' at the University of Stuttgart is gratefully acknowledged. For assistance with the processing of the manuscript my special thanks are due to Mrs Angela Winkelmann and Dr. Brigitte Schwederski.

Part 1

Biological Systems

1 Electron Transfer in Metalloproteins

Harry B. Gray and Jay R. Winkler

1.1 Introduction

Electron transfer (ET) reactions are key steps in a great many biological processes [1]. The urgent demands of life impose stringent requirements on the speed and specificity of these transformations. A vast array of redox enzymes, often containing transition metal cofactors, has evolved to meet the narrow tolerances associated with biological electron flow. In these proteins, electrons transfer rapidly (<ms) over distances as great as 20 Å, with little release of free energy [2]. It is reasonable to question whether these elaborate structures are necessary to sustain electron flow and, if so, how do folded polypeptides accomplish this task?

1.2 The Semiclassical Model of Electron Transfer

Theoretical efforts beginning in the late 1950s and continuing to the present day have provided a remarkably detailed description of ET reactions [3]. The semiclassical model (Eq. 1) describes the first-order rate constant for electron transfer from a donor

$$k_{\text{ET}} = \sqrt{\frac{4\pi^3}{h^2 \lambda k_B T}} H_{\text{AB}}^2 \exp \left\{ -\frac{(\Delta G^\circ + \lambda)^2}{4\lambda k_B T} \right\} \quad (1)$$

(**D**) to an acceptor (**A**) held at fixed distance and orientation as a function of temperature (*T*), reaction driving force ($-\Delta G^\circ$), a nuclear reorganization parameter (λ), and electronic coupling matrix element (H_{AB}). The reorganization parameter reflects the changes in structure and solvation that result when an electron moves from **D** to **A**. A balance between nuclear reorganization and reaction driving force

determines both the transition-state configuration and the height of the barrier to the ET process. At the optimum driving force ($-\Delta G^\circ = \lambda$), rates become activationless (k_{ET}°), limited only by the strength of the **D/A** interaction. When **D** and **A** are in van der Waals contact, the coupling strength is usually so large that ET occurs every time the transition-state configuration is formed. In this adiabatic limit, the ET rate is independent of H_{AB} and the prefactor depends only on the frequency of motion along the reaction coordinate. The nonadiabatic limit (Eq. 1) obtains when the **D/A** interaction is weak and the transition state must be reached many times before an electron is transferred. The electronic coupling element measures the frequency of crossing from reactants (**D** + **A**) to products (**D**⁺ + **A**[−]) in the region of the transition state.

The barriers to electron exchange between hydrated transition metal ions are readily interpreted in terms of the semiclassical theory [3]. The 0.67-eV activation energy for electron exchange between aquo ferrous and ferric complexes, for example, implies a 2.7-eV reorganization energy. The major contribution (1.5 eV) is attributed to the 0.14-Å difference in Fe–O bond lengths in the ferric and ferrous ions. The remainder (1.2 eV) arises from repolarization of the aqueous solvent upon electron transfer. When the ferrous and ferric ions are in contact, this large reorganization energy leads to a 30-ms time constant for electron exchange. Even at short range, then, the barriers to ET between hydrated metal ions are too great for the demands of biological electron flow. To reduce the reorganization energy, proteins must sequester the redox-active metals in hydrophobic cavities, away from the polar aqueous solvent. In this way, a three-fold decrease in reorganization energy can be achieved, decreasing the time constant for electron exchange by over seven orders of magnitude (Figure 1).

Figure 1. Schematic representation of the free-energy surfaces for electron exchange between hydrated ferrous and ferric ions in aqueous solution and between the ions complexed in a protein.

The singular feature of electron transfer is that reactions can proceed at very high rates when **D** and **A** are separated by long distances. The electron tunnels through a potential barrier between **D** and **A**; for a square barrier, H_{AB} displays an exponential dependence on the distance between the reactants (**R**) [4]. The medium between redox centers is vitally important for long-range ET. Owing to an estimated $3.5\text{-}\text{\AA}^{-1}$ distance decay constant (β), the time required for electron exchange between hydrated ferrous and ferric ions balloons to almost 10^{17} years if the complexes are separated by $20\text{ }\text{\AA}$ in a vacuum [5]. Superexchange coupling via hole and electron states of the intervening medium enhances the **D/A** electronic interaction and produces a more gradual decrease in rate with distance [6–8]. Fill the void between hydrated ferrous and ferric ions with water ($\beta = 1.68\text{ }\text{\AA}^{-1}$) [9] and the time constant for $20\text{-}\text{\AA}$ electron exchange decreases dramatically (2×10^3 years), but is still far too slow to support biological activity. It is clear, then, that in addition to lowering reorganization barriers, the protein must play a pivotal electronic coupling role. The question is the following: how does a heterogeneous array of covalent and non-covalent contacts in a folded polypeptide mediate long-range electronic coupling?

1.3 Ru-Modified Proteins

Investigations of protein–protein ET reactions have provided important insights into biological electron flow [10–14]. Natural systems, however, often are not amenable to the systematic studies that are required for evaluation of the key ET parameters λ and H_{AB} . A successful alternative approach involves measurements of ET in metalloproteins that have been labeled with redox-active molecules [15–19]. By varying the binding site and chemical composition of the probe molecule, it has been possible to elucidate the factors that control the rates of long-range ET reactions in proteins.

Ruthenium complexes are excellent reagents for protein modification and electron-transfer studies. Ru^{2+} -aquo complexes readily react with surface His residues on proteins to form stable derivatives [20, 21]. Low-spin pseudo-octahedral Ru-complexes exhibit small structural changes upon redox cycling between the Ru^{2+} and Ru^{3+} formal oxidation states [3, 22]. Hence, the inner-sphere barriers to electron transfer (λ_1) are small. With the appropriate choice of ligand, the $\text{Ru}^{3+/2+}$ reduction potential can be varied from <0.0 to >1.5 V versus NHE [23]. Ru-bpy complexes bound to Lys and Cys residues have been employed to great advantage in studies of protein–protein ET reactions. The kinetics of electron transfer in cytochrome *b*₅/cytochrome *c* [24], cytochrome *c*/cytochrome *c* peroxidase [12], and cytochrome *c*/cytochrome *c* oxidase [25] complexes have been measured with the aid of laser-initiated ET from a Ru-bpy label.

A great deal of work on Ru-modified proteins has employed the $\text{Ru}(\text{bpy})_2(\text{im})$ (HisX)²⁺ (bpy = 2,2'-bipyridine; im = imidazole) label [16, 21, 26] (Figure 2). In addition to favorable ET properties, these Ru-bpy complexes have long-lived, luminescent metal-to-ligand charge-transfer excited states that can be prepared with

Figure 2. Ribbon structure representation of the crystal structure of $\text{Ru}(\text{bpy})_2(\text{im})(\text{His83})^{2+}$ -labeled *Pseudomonas aeruginosa* azurin [26].

short laser pulses. These excited states enable a wider range of ET measurements than is possible with nonluminescent complexes. Furthermore, the bpy ligands raise the $\text{Ru}^{3+/2+}$ reduction potential (>1 V versus NHE) so that observed ET rates are close to k_{ET}° , improving the reliability of H_{AB} and λ determinations.

1.4 Reorganization Energy

The semiclassical ET model predicts that rates will depend on reaction driving force and temperature [3]. Investigations of the dependences of ET rates on either of these two parameters can be used to obtain reorganization energies. Although conceptually straightforward, both methods have difficulties. In order to vary the reaction driving force, changes in one or both redox sites are required. These chemical modifications must be chosen with care to ensure that λ does not change along with ΔG° . Studies of the temperature dependence of k_{ET} are easier in principle, but will not provide accurate λ values unless the temperature dependence of ΔG° is determined as well [3, 27].

1.4.1 Cytochrome *c*

ET in a Ru-modified protein was first measured in $\text{Ru}(\text{NH}_3)_5(\text{His33})^{3+}$ -ferricytochrome *c* [28]. The rate of Ru^{2+} to Fe^{3+} electron transfer over a distance of 18 \AA at

Figure 3. Driving force-dependence of intramolecular electron transfer rates in Ru-ammine-His33 modified Zn-substituted cytochrome *c* (■), and Ru-bpy-His33 modified Fe-cytochrome *c* (●). Solid lines were generated using Eq. 1 and the following parameters: Ru-ammine, $\lambda = 1.15$ eV, $H_{AB} = 0.10$ cm⁻¹; Ru-bpy, $\lambda = 0.74$ eV, $H_{AB} = 0.095$ cm⁻¹.

a driving force of 0.2 eV is 30 s⁻¹. Replacement of the native Fe center in the heme with Zn paved the way for ET measurements at higher driving forces [15, 29, 30]. Indeed, replacement of a heme center with a Zn-porphyrin has provided many opportunities for investigations of *interprotein* ET reactions. Hoffman and co-workers have used this technique in their work on ET in hybrid hemoglobins and cytochrome *c*/cytochrome *c* peroxidase complexes [10], and Zn-substituted cytochrome *c* has been exploited in studies of conformationally regulated ET in cytochrome *c*/plastocyanin complexes [14]. The driving-force dependence of *intraprotein* ET rates in Ru(NH₃)₄L(His33)-Zn-cytochrome *c* (L = NH₃, pyridine, isonicotinamide) yielded the parameters $\lambda = 1.15$ eV and $H_{AB} = 0.1$ cm⁻¹ [15, 30] (Figure 3). The Marcus cross-relation ($\lambda_{12} = \frac{1}{2}[\lambda_{11} + \lambda_{22}]$) describes the reorganization energy for the reaction between **D** and **A** (λ_{12}) as the mean of the reorganization energies for electron exchange between **D** and **D**⁺ (λ_{11}) and exchange between **A** and **A**⁻ (λ_{22}) [3]. The Fe-cytochrome *c* self-exchange reorganization energy has been estimated to be 0.7 eV [31]. If the Zn-cytochrome *c* reorganization energy is comparable to that of the Fe protein, then it is apparent that the hydrophilic Ru-ammine complex is responsible for about two-thirds of the total reorganization energy in Ru-ammine-modified cytochrome *c* ET reactions ($\lambda(\text{Ru}^{3+/2+}) = 1.7$ eV). This result is in good agreement with estimates of the self-exchange reorganization energy in Ru(NH₃)₆^{3+/2+} [3, 22].

Studies of self-exchange reactions have demonstrated that replacing ammonia

ligands with diimine ligands substantially reduces the reorganization energy associated with $\text{Ru}^{3+/2+}$ ET [3, 22]. The difference can be attributed to a decrease in solvent polarization by the larger Ru-diimine ions, and to somewhat smaller inner-sphere barriers as well. It was expected, then, that the reorganization energy for ET in $\text{Ru}(\text{bpy})_2(\text{im})(\text{His33})\text{-Fe-cytochrome } c$ would be less than 1.15 eV. Indeed, a study of the driving-force dependence of $\text{Fe}^{2+} \rightarrow \text{Ru}^{3+}$ ET rates in $\text{Ru}(\text{LL})_2(\text{im})(\text{His33})\text{-Fe-cytochrome } c$ (LL = bpy, 4,4'-(CH_3)₂-bpy, 4,4',5,5'-(CH_3)₄-bpy, 4,4'-(CONH(C_2H_5))₂-bpy) gave $\lambda = 0.74$ eV and $H_{\text{AB}} = 0.095$ cm⁻¹ [32, 33]. The 0.4-eV decrease in reorganization energy resulting from replacement of the Ru-ammine complex with a Ru-bpy label is in excellent agreement with estimates from cross-reactions of model complexes [3, 22].

The large difference in reorganization energy between Ru-ammine and Ru-bpy modified cytochromes highlights the important role of water in protein electron transfer. The bulky bpy ligands shield the charged metal center from the polar aqueous solution, reducing the solvent reorganization energy. In the same manner, the medium surrounding a metalloprotein active site will affect the reorganization energy associated with its ET reactions. A hydrophilic active site will lead to larger reorganization energies than a hydrophobic site. Consequently, the kinetics of protein ET reactions will be very sensitive to the active-site environment.

The exponential factor in Eq. 1 reflects the interplay between driving force and reorganization energy that regulates ET rates. The remarkable prediction of the semiclassical ET model is that rates reach a maximum value as a function of driving force ($-\Delta G^\circ = \lambda$). At low driving forces, rates increase with $-\Delta G^\circ$ but, at very high driving forces ($-\Delta G^\circ > \lambda$), ET rates are expected to decrease (inverted effect). Experimental studies of ET rates in synthetic model complexes [34–36] and in biological systems [19, 33, 37] have provided convincing evidence for inverted driving-force effects. Importantly, a reaction in the inverted region can be accelerated if a pathway is available that releases less free energy in the actual ET step [38]. This can be accomplished by the formation of electronically excited products ($^*\text{D}^+$, $^*\text{A}^-$), because the ET driving force will be lower by an amount equal to the energy of the excited electronic state. An ET process that forms excited products will be the preferred pathway if its driving force is closer to λ than that of a reaction forming ground-state products. Chemiluminescent ET reactions are a familiar example of such processes and are a clear demonstration of the inverted effect [3].

The rates of heme reduction by $^*\text{Ru}^{2+}$ and Ru^+ in $\text{Ru}(\text{His33})\text{cytochrome } c$ have been examined at very high driving forces ($1.3 \text{ eV} \leq -\Delta G^\circ \leq 1.9 \text{ eV}$) [33]. The semiclassical model predicts significant inverted effects in this region, but at driving forces above 1.3 eV rates leveled at a value eight-fold below the maximum ET rate. Rate/energy leveling is a common phenomenon, particularly in excited-state ET reactions; formation of electronically excited products is a likely explanation for the absence of inverted effects [38]. In the case of cytochrome *c* heme reduction by Ru^+ , reactions that form low-lying metal-to-ligand charge transfer excited states of the ferroheme ($\text{Fe}(d\pi) \rightarrow \text{porphyrin}(\pi^*)$; 1.05–1.3 eV) should be faster than reactions forming ground-state products. The low-lying excited states of ferro- and ferrihemes are likely to mask inverted driving-force effects in the ET reactions of heme proteins.

1.4.2 Azurin

The remarkable properties of the blue copper active site in azurin and related proteins have been studied for nearly five decades [39, 40]. Hydrated copper ions and synthetic Cu complexes tend to be rather sluggish redox reagents because of large structural changes that accompany electron transfer [40–42]. The structure of the active site in blue copper proteins, by contrast, is the same in both oxidation states of the protein [40, 43]. Whether this structural invariance is an intrinsic property of the ligand set or is enforced by the protein fold has been a hotly debated topic [40, 44–47]. Regardless of its origin, this active-site property enables copper to transfer electrons rapidly owing to a low ($\text{Cu}^{2+}/\text{Cu}^+$) reorganization energy [48].

Measurements of the temperature dependence of the rate of $\text{Cu}^+ \rightarrow \text{Ru}^{3+}$ ET in $\text{Ru}(\text{bpy})_2(\text{im})(\text{His83})\text{azurin}$ between 170 and 308 K have been used to determine the reorganization energy for electron exchange in the protein. Between 276 and 308 K, ET rates are temperature-invariant [49]. More remarkable was the observation that the $\text{Cu}^+ \rightarrow \text{Ru}^{3+}$ ET rate at 170 K is slightly greater than that measured at room temperature [50] (Figure 4). Data over this wide temperature range, along with determinations of the temperature dependence of ΔG° , constrain λ to a value of 0.7 ± 0.1 eV. The reorganization energy for $\text{Cu}^+ \rightarrow \text{Ru}(\text{LL})_2(\text{im})(\text{His83})^{3+}$ ET in azurin is the same, within error, as that for $\text{Fe}^{2+} \rightarrow \text{Ru}(\text{LL})_2(\text{im})(\text{His33})^{3+}$ ET in cytochrome *c*, indicating that the two redox proteins have comparable self-exchange reorganization energies (0.7 ± 0.1 eV). The fact that the reorganization energy for electron exchange in $\text{Cu}(\text{phen})_2^{2+/+}$ [42] is almost 2 eV greater than that for azurin illustrates the important role played by the folded polypeptide in lowering barriers to ET reactions [48].

Figure 4. Temperature dependence of Cu^+ to Ru^{3+} ET rates in $\text{Ru}(\text{bpy})_2(\text{im})(\text{His83})^{2+}$ -azurin. Lines were calculated using Eq. 1 with $H_{\text{AB}} = 0.07 \text{ cm}^{-1}$ and $\lambda = 0.7$ eV (solid line); 0.5 eV (dashed line); and 1.0 eV (dotted line).

1.5 Electronic Coupling

1.5.1 Theoretical Models

Nonadiabatic ET reactions are characterized by weak electronic interaction between the reactants and products at the transition-state nuclear configuration ($H_{AB} \ll k_B T$). This coupling is directly related to the strength of the electronic interaction between the donor and acceptor [51]. When donors and acceptors are separated by long distances ($>10 \text{ \AA}$), direct overlap of their wavefunctions will be vanishingly small; the material between the two redox sites must mediate the coupling.

Uniform-barrier models

In 1974, Hopfield described biological ET in terms of electron tunneling through a square potential barrier [4]. In this model, H_{AB}^2 (and, hence, k_{ET}) drops off exponentially with increasing D/A separation. The height of the tunneling barrier relative to the energies of the D/A states determines the distance decay constant (β). Hopfield estimated $\beta \sim 1.4 \text{ \AA}^{-1}$ for biological ET reactions on the basis of measurements of the temperature dependence of ET from a cytochrome to the oxidized special pair in the photosynthetic reaction center of *Chromatium vinosum*. This calculation was performed before the reaction center structure had been determined. The analysis suggested an 8- \AA edge-edge separation; later structural studies revealed that the actual distance was somewhat greater (12.3 \AA) [52].

Superexchange-coupling models

Superexchange models are often employed to describe long-range electronic couplings; electronic states of the intervening bridge mediate the D/A interaction. If oxidized states of the bridge mediate the coupling, the process is referred to as “hole transfer”; mediation by reduced bridge states is known as “electron transfer”. In 1961, McConnell developed a nearest-neighbor superexchange coupling model to describe charge-transfer interactions between donors and acceptors separated by spacers comprised of identical repeat units [53]. The total coupling (H_{AB}) is given as the product of the coupling decays for each bridge site (ϵ). For a bridge built from identical repeat units separated by m bonds, H_{AB} will be proportional to ϵ^m . In this model, the ET rate constant will exhibit an exponential dependence on the number of bonds separating D and A; experimental studies on synthetic D-br-A complexes support this prediction.

Ab initio calculations of H_{AB} for bridges composed of saturated alkane spacers suggest that the simple superexchange model is not quantitatively accurate [54–56]. Nonnearest-neighbor interactions were found to dominate the couplings and, except in a few cases, nearest-neighbor interactions were relatively unimportant. A particularly significant finding is that the nonnearest neighbor interactions make the coupling along a saturated alkane bridge quite sensitive to its conformation.

The medium separating redox sites in proteins is comprised of a complex array of

bonded and nonbonded contacts, and an *ab initio* calculation of coupling strengths is a formidable challenge. The homologous-bridge (McConnell) superexchange model is not suitable because of the diverse interactions in proteins. Beratan, Onuchic, and coworkers developed a generalized tunneling pathway (TP) superexchange coupling model that accommodates the structural complexity of a protein matrix [57–60]. The TP model reduces the diverse interactions between the atoms in a folded polypeptide to a set of three types of contacts: covalent bonds, hydrogen bonds, and through space contacts. Each type of contact is assigned a coupling decay value (ε_C , ε_H , and ε_S) which permits implementation of a search algorithm for finding optimal coupling pathways through proteins. The total coupling of a single pathway is given as a product of the couplings for the individual links (Eq. 2) [5].

$$H_{AB} \propto \prod \varepsilon_C \prod \varepsilon_H \prod \varepsilon_S \quad (2)$$

A tunneling pathway can be described in terms of an effective covalent tunneling path comprised of n (nonintegral) covalent bonds, with a total length equal to σ_1 (Eq. 3). The relationship between σ_1 and the direct **D**–**A** distance (**R**) reflects

$$H_{AB} \propto (\varepsilon_C)^n \quad (3a)$$

$$\sigma_1 = n \times 1.4 \text{ \AA/bond} \quad (3b)$$

the coupling efficiency of a pathway. The variation of ET rates with **R** is expected to depend upon the coupling decay for a single covalent bond (ε_C); the magnitude of ε_C depends critically upon the energy of the tunneling electron relative to the energies of the bridge hole and electron states.

Distance dependences of ET rates

The **D**–**A** distance decay of protein ET rate constants depends on the capacity of the polypeptide matrix to mediate distant electronic couplings. If dominant coupling pathways mediate long-range electron transfer in proteins, then single-site mutations could have profound effects on enzyme function. In addition, if single pathways operate in biological ET reactions, then they have presumably been optimized through natural selection. These consequences of tunneling pathways impart a certain lack of robustness into the protein structure–function relationship. Concerns about this issue led Dutton and coworkers to propose that a folded polypeptide matrix behaves like a glassy solvent, imposing a uniform barrier (UB) to electron tunneling [52, 61]. Analysis of a variety of ET rates—especially those from the photosynthetic reaction center—produced a universal distance decay constant for protein electron transfer that was in remarkable agreement with Hopfield’s 1974 estimate (1.4 \AA^{-1}) [52]. Disagreements over the appropriate **D/A** distance measure (edge-to-edge, center-to-center) fueled disputes about whether the large body of protein ET data supports a homogeneous barrier model, or whether a structure-dependent model is necessary. Recently, the UB model has been amended to include the packing density of the protein matrix [62]. Although this model ignores

bond connectivity, it does embody many of the same elements as the TP model by accounting for, in a rudimentary fashion, the protein structure dependence of long-range couplings.

The great strength of the TP model is that a straightforward analysis of a protein structure identifies residues that are important for mediating long-range coupling. Employing this model, Beratan, Betts, and Onuchic predicted in 1991 that proteins comprised largely of β -sheet structures would be more effective at mediating long-range couplings than those built from α helices [58]. This analysis can be taken a step further by comparing the coupling efficiencies of individual protein secondary structural elements (β sheets, α helices). The coupling efficiency can be determined from the variation of σ_1 as a function of \mathbf{R} . A linear σ_1/\mathbf{R} relationship implies that k_{ET}° will be an exponential function of \mathbf{R} ; the distance decay constant is determined by the slope of the σ_1/\mathbf{R} plot and the value of ϵ_C [16].

A β sheet is comprised of extended polypeptide chains interconnected by hydrogen bonds; the individual strands of β sheets define nearly linear coupling pathways along the peptide backbone spanning 3.4 Å per residue. The tunneling length for a β strand exhibits an excellent linear correlation with β -carbon separation (R_β); the best linear fit with zero intercept yields a slope of 1.37 σ_1/R_β (distance decay constant = 1.0 Å⁻¹) (Figure 5). Couplings across a β sheet depend upon the ability of hydrogen bonds to mediate the D/A interaction. The standard parameterization of the TP model defines the coupling decay across a hydrogen bond in terms of the

Figure 5. Plot of calculated tunneling path length (σ_1) versus β -carbon separation (R_β) for ET along an idealized α helix (■, using the standard H-bond coupling parameters in the TP model) and a β strand (●).

heteroatom separation. If the two heteroatoms are separated by twice the 1.4-Å covalent-bond distance, then the hydrogen-bond decay is assigned a value equal to that of a covalent bond. Longer heteroatom separations lead to weaker predicted couplings but, as yet, there is no experimental confirmation of this relationship.

In the coiled α -helix structure a linear distance of just 1.5 Å is spanned per residue. In the absence of mediation by hydrogen bonds, σ_1 is a very steep function of R_β , implying that an α helix is a poor conductor of electronic coupling ($2.7 \sigma_1/R_\beta$, distance decay constant = 1.97 Å^{-1}). If the hydrogen-bond networks in α helices mediate coupling, then the Beratan–Onuchic parameterization of hydrogen-bond couplings suggests a σ_1/R_β ratio of 1.72 (distance decay constant = 1.26 Å^{-1}) (Figure 5). Treating hydrogen bonds as covalent bonds further reduces this ratio ($1.29 \sigma_1/R_\beta$, distance decay constant = 0.94 Å^{-1}). Hydrogen-bond interactions, then, will determine whether α helices are vastly inferior to or are slightly better than β sheets in mediating long-range electronic couplings. It is important to note that the coiled helical structure leads to poorer σ_1/R_β correlations, especially for values of R_β under 10 Å. In this distance region, the TP model predicts little variation in coupling efficiencies for the different secondary structures.

Analyses of ET rate/distance relationships require a consistent definition of the D/A distance [63–65]. When comparing rates from systems with different donors and/or acceptors, it can be difficult to identify a proper distance measure. All maximum ET rates should extrapolate to a common adiabatic rate as R approaches van der Waals contact. So-called edge-to-edge distances are often employed but there are many ambiguities, not the least of which is defining the set of atoms that constitute the edges of **D** and **A**. For planar aromatic molecules (e.g., chlorophylls, pheophytins, quinones), edge–edge separations are usually defined on the basis of the shortest distance between aromatic carbon atoms of **D** and **A**. In transition-metal complexes (e.g., Fe-heme, Ru-ammine, Ru-bpy), however, atoms on the periphery are not always well coupled to the central metal, and empirical evidence suggests that metal–metal distances are more appropriate.

1.5.2 Blue Copper Proteins

Azurin

In azurin, a prototypal blue protein with a β -barrel tertiary structure, the central Cu atom is coordinated to Cys112 (S), His117 (N), and His46 (N) donor atoms in a trigonal planar structure, with weakly interacting Met121 (S) and Gly45 (carbonyl O atom) ligands above and below the plane [66, 67]. Individual β strands extend from these ligands, forming a β sheet. Coupling-limited rates (k_{ET}^0) have been obtained for Ru-modified azurin mutants with His residues at different sites on the β strands extending from Met121 (His122, His124, His126) and Cys112 (His109, His107) [49, 50, 68–70]. The variation of tunneling time with the Cu–Ru separation (distance decay constant of 1.1 Å^{-1}) is in remarkably good agreement with the predicted value of 1.0 Å^{-1} for a strand of an ideal β sheet (Figure 6). Detailed electronic structure calculations indicate that the S atom of Cys112 has by far the

Figure 6. Tunneling timetable for ET in Ru-modified azurin. The solid line is the TP prediction for coupling along a β strand ($\beta = 1.0 \text{ \AA}^{-1}$); the dashed line illustrates a 1.1 \AA^{-1} distance decay.

strongest coupling to the Cu center; the His (imidazole) couplings are only one-third that of the Cys ligand, and the Met121 (S) and Gly45 (O) couplings are just one-tenth of the Cys coupling [71, 72]. These highly anisotropic ligand interactions strongly favor pathways that couple to the Cu through Cys112. Couplings along different β strands would be expected to have the same distance-decay constants, but different intercepts at close contact. Relatively strong Cu/Ru couplings also have been found for ET reactions involving Ru-modified His83 [49, 50, 69]. Given the variations in structure and composition of intervening media, it is somewhat surprising that the distance dependence of ET in Ru-modified azurin can be described by a single straight line.

One explanation for uniform distance dependence of couplings along the Met121 and Cys112 strands is that strong interstrand hydrogen bonds serve to direct all of the distant couplings through the Cys112 ligand [69, 73, 74]. A hydrogen bond between Met121(O) and Cys112(NH) could mediate coupling from the Ru complex bound to His122. A second hydrogen bond (Gly123(O)–Phe110(NH)) would provide a coupling link for His124 and His126 ET reactions. The importance of the pathways that cross from the Met121 strand to the Cys112 strand depends upon the coupling efficiencies of the hydrogen bonds. Model-complex studies have demonstrated efficient electron transfer across hydrogen-bonded interfaces [75, 76]. In the standard Beratan–Onuchic pathway model, hydrogen-bond couplings are distance-scaled and generally afford weaker couplings than covalent bonds [5]. This procedure for calculating hydrogen-bond couplings cannot explain the similar distance dependences of ET along the Met121 and Cys112 strands in Ru-modified azurins.

Treating the hydrogen bonds as covalent bonds in the TP model ($\epsilon_H = \epsilon_C^2$), however, does lead to better agreement with experiment [69].

Long-range ET from the Cys3–Cys26 disulfide radical anion to the copper in azurin has been studied extensively by Farver and Pecht [77]. Estimates based on experimental rate data indicate that the S_2/Cu coupling is unusually strong for a donor/acceptor pair separated by 26 Å. Interestingly, both the Cys3–Cys26 and His83 tunneling times fit on the 1.1 Å^{-1} distance decay defined by the couplings along the Met121 and Cys112 strands. Similar methods have been employed to study the ET properties of a Cu_A site constructed in azurin [78].

Plastocyanin

Rates of Cu^+ to Ru^{3+} electron transfer also have been measured in modified mutants of spinach plastocyanin, a blue copper protein from the photosynthetic ET chain [79]. Ru–bipyridine complexes were introduced at surface sites, with Cu–Ru distances ranging from 13 to 24 Å. ET rate constants, measured using laser flash-quench techniques, vary from 10^4 to 10^7 s^{-1} . ET in Ru-modified plastocyanin is not activationless as it is in Ru-modified azurin, suggesting a slightly greater reorganization energy for the photosynthetic protein. The distance dependence of ET in Ru-modified plastocyanin is exponential with a distance decay factor identical with that reported for Ru-modified azurin (1.1 Å^{-1}).

The reduced forms of several blue copper proteins are known to undergo a pH-dependent change in Cu-ligation; the pK_a values for these transformations lie in the 5–7 range. In the low-pH forms of these proteins an imidazole ligand dissociates from the Cu center and is protonated [80]. The reduction potential of the Cu site in the low-pH form of the protein, owing to the trigonal coordination geometry composed of S(Cys), N(His) and S(Met) ligands, is substantially greater than that of the neutral-pH form. The pH dependence of Cu^+ to Ru^{3+} ET has been examined in *Scenedesmus obliquus* plastocyanin labeled with a Ru complex at His59 ($Ru(tpy)(bpy)(His59)^{2+}$) [81]. The pK_a for His87 dissociation in the reduced form of this protein is 5.5 [82]. At pH 7, the Cu^+ to Ru^{3+} ET rate is $2.9(2) \times 10^7 \text{ s}^{-1}$. Biphasic ET kinetics are observed in acidic solutions (pH 5.6–4.1). The rate for the faster phase agrees well with that measured at pH 7, and has been attributed to oxidation of a population of protein in the high-pH form. The slower phase corresponds to oxidation of the low-pH, trigonal Cu sites. The strong temperature and pH dependences of the slower reaction suggest that Cu^+ rearranges to the high-pH tetrahedral geometry prior to electron transfer to Ru^{3+} [80].

1.5.3 Heme Proteins

Cytochrome *c*

ET rates have been measured in eight different $Ru(bpy)_2(im)(HisX)^{2+}$ derivatives of wild-type and mutant cytochromes *c* [16, 32, 68, 83]. Maximum ET rates do not correlate well with a simple exponential distance dependence (Figure 7). Two modified proteins, for example, have comparable ET rates ($Ru(His72)$, $9.0 \times 10^5 \text{ s}^{-1}$;

Figure 7. Tunneling timetable for ET in Ru-modified cytochrome *c*. The solid line illustrates a 1.05 Å^{-1} distance decay.

Ru(His39), $3.2 \times 10^6 \text{ s}^{-1}$), yet the Ru-Fe distances differ by 6.5 Å (His72, 13.8 Å ; His39, 20.3 Å). Moreover, the D/A distances in the Ru(His39) and Ru(His62) derivatives are nearly identical (20.3 and 20.2 Å , respectively), yet their maximum ET rates differ by a factor of 300 (3.2×10^6 and $1.0 \times 10^4 \text{ s}^{-1}$, respectively). The scatter in the data illustrates conclusively that the UB model does not adequately describe long-range couplings in proteins; a model that takes into account the structure of the bridging medium is required to explain the data.

Myoglobin

Donor–acceptor pairs separated by α helices include the heme-Ru redox sites in two Ru-modified myoglobins, Ru(bpy)₂(im)(HisX)-Mb (X = 83, 95) [70]. The tunneling pathway from His95 to the Mb-heme is comprised of a short section of α helix terminating at His93, the heme axial ligand. The coupling for the $[\text{Fe}^{2+} \rightarrow \text{Ru}^{3+}(\text{His95})]\text{-Mb}$ ET reaction [70] is of the same magnitude as that found in Ru-modified azurins with comparable D–A spacings. This result is consistent with the TP model, which predicts very little difference in the coupling efficiencies of α helices and β sheets at small D–A separations. The $[\text{Fe}^{2+} \rightarrow \text{Ru}^{3+}(\text{His83})]\text{-Mb}$ [70] tunneling time, however, is substantially longer than those found in β -sheet structures at similar separations, in accord with the predicted distance decay constant for an α helix (Figure 8).

Cytochrome *b*₅₆₂

ET rate data are available for nine Ru-modified derivatives of cytochrome *b*₅₆₂, a four-helix-bundle protein [84]. The tunneling times for Ru-modified *b*₅₆₂ exhibit far

Figure 8. Tunneling timetable for ET in Ru-modified myoglobin (◆) and cytochrome b_{562} (●). The solid lines illustrate the TP predictions for coupling along β strands ($\beta = 1.0 \text{ Å}^{-1}$) and α helices ($\beta = 1.3 \text{ Å}^{-1}$).

more scatter than was found for Ru-modified azurin. Two derivatives exhibit ET rates close to those predicted for coupling along a simple α helix, and several others lie close to the β -strand decay (Figure 8). In these proteins, as in Ru(His70)Mb, the intervening medium is not a simple section of α helix. Coupling across helices, perhaps on multiple interfering pathways, is likely to produce a complex distance dependence. Interpretation of the relative ET rates in cytochrome b_{562} will require a more detailed analysis of the medium separating the redox sites [85].

1.5.4 High-Potential Iron-Sulfur Protein (HiPIP)

Results with Ru-modified HiPIP provide additional evidence for structure-dependent couplings [86]. The Ru(His42) and Ru(His50) derivatives of this protein have metal–metal separations of 12 Å , yet the rate of ET from the reduced $[\text{Fe}_4\text{S}_4]$ cluster to Ru^{3+} is 300 times slower in the Ru(His50) derivative. The poor coupling in Ru(His50) has been attributed to a 3.8 Å through-space gap in the optimum Fe–Ru pathway.

1.6 Electron Tunneling through Water

Very little consideration has been given to the involvement of solvent hole and electron states [87–89] in the mediation of distant couplings in proteins. In fluid

solution, when the positions of **D** and **A** are not constrained by a covalent bridge, diffusion places an upper limit on the time scale ($<10^{-9}$ s) and, therefore, the distance range (<9 Å for $\beta = 1.0$ Å $^{-1}$) for electron tunneling. Nevertheless, analyses of non-exponential fluorescence-quenching kinetics are consistent with $\beta = 1.2 \pm 0.2$ Å $^{-1}$ for tunneling through fluid organic solvents [90]. Longer tunneling distances can be examined if **D** and **A** are immobilized. Pulse radiolysis and photochemical investigations of intermolecular electron transfer in aqueous and organic glasses have produced β values in the 0.75–1.4 Å $^{-1}$ range [91, 92].

Although immobilizing **D** and **A** eliminates the problem of diffusion, it introduces complications into the analysis of the kinetics data. In a typical experiment, a small concentration of electron or hole donors is embedded in a glassed solvent amid a higher concentration of randomly distributed acceptors. The donor is a photo-excited chromophore or a radiolytically generated radical. The time-dependent survival probability of the donor depends on the concentration of acceptors, the rate constant for electron/hole transfer when **D** and **A** are in van der Waals contact (k_0), and the distance decay factor β . Extracting reliable values for k_0 and β from time-resolved spectroscopic measurements, however, can be rather difficult because the two parameters are highly correlated [90, 93]. For the case of photoinitiated ET in glasses, measurements of luminescence decay kinetics *and* luminescence quantum yields at several different quencher concentrations provide enough information to decouple k_0 and β , permitting reliable values to be determined for each parameter [90].

The relevant solvent for protein electron transfer is water. Indeed, aqueous-solution redox processes pervade chemistry and biology and ET reactions in water have been among the most intensively studied [1, 3, 94]. The high dielectric constant of water has long been recognized to impose large reorganization barriers to ET [3], but little is known about its ability to mediate long-range couplings [88, 89, 95]. In 1984, Larsson suggested that long-range ET in water would be inefficient ($\beta = 2.4$ Å $^{-1}$) because of the large energy gap between the hole states of water and those of **D** and **A** [96]. More recent theoretical treatments, however, have produced β values in the 1.0 to 1.8 Å $^{-1}$ range [88, 97, 98].

An experimental investigation of $\text{Ru}(\text{tpy})_2^{2+}$ (tpy = 2,2':6,2''-terpyridine) luminescence quenching by $\text{Fe}(\text{OH}_2)_6^{3+}$ in aqueous acidic glasses has placed rigorous limits on the distance decay constant for tunneling through water [9]. In the absence of quenchers, the luminescence lifetime of $\text{Ru}(\text{tpy})_2^{2+}$ is 8.0 μs in $\text{H}_2\text{SO}_4/\text{H}_2\text{O}$ and $\text{HSO}_3\text{F}/\text{H}_2\text{O}$ glasses (25 %, v/v) at 77 K, and 10.2 μs in $\text{D}_2\text{SO}_4/\text{D}_2\text{O}$ (25 %, v/v). Addition of moderate concentrations of the powerfully oxidizing $\text{Fe}(\text{OH}_2)_6^{3+}$ ion (0.01–0.5 M, $E^\circ = 0.77$ V versus NHE[99]) to the glasses leads to accelerated and highly nonexponential $^*\text{Ru}(\text{tpy})_2^{2+}$ decay kinetics. Distance decay constants for $\text{Fe}(\text{OH}_2)_6^{3+}$ quenching of $^*\text{Ru}(\text{tpy})_2^{2+}$ in aqueous glasses were extracted from measurements of luminescence decay kinetics as functions of quencher concentration. The luminescence lifetime of $^*\text{Ru}(\text{tpy})_2^{2+}$ in aqueous glasses is long enough to allow a significant distance range (~ 25 Å) to be probed. Quantum-yield data were used to scale the intensities of the decay kinetics so that just two parameters were required to fit the data. A distance decay constant of 1.68 ± 0.07 Å $^{-1}$ adequately describes ET in the three different glasses, and the rate constants for ET at van der

Waals contact are approximately 10^{13} s^{-1} . Although large concentrations of acid (25 %, v/v) are required for vitrification, water is still the dominant component in these matrices. On a molar basis, the acidic glasses are greater than 90 % $\text{H}_2\text{O}/\text{H}_3\text{O}^+$. The fact that the distance decay parameter in the HSO_3F glass is virtually identical with that obtained in the H_2SO_4 glass provides additional evidence that the oxo anions are not playing an important coupling role.

The distance decay factor for tunneling through water provides an interesting comparison to results from **D-br-A** complexes. ET across saturated alkane spacers is best described by an exponential distance decay constant of 0.9 \AA^{-1} [6]. The $1.2\text{-}\text{\AA}^{-1}$ β value reported for tunneling in 2-methyl tetrahydrofuran glasses can be explained by weaker coupling between solvent molecules than between adjacent carbon atoms in the covalently bonded alkane chain. The average distance decay constant found for tunneling through proteins is 1.1 \AA^{-1} , although there is significant deviation from a simple exponential distance dependence because proteins do not provide a homogeneous tunneling barrier. The region representing the distance decay for coupling through water ($\beta = 1.61\text{--}1.75 \text{ \AA}^{-1}$) demonstrates that, although better than a vacuum ($\beta = 3\text{--}4 \text{ \AA}^{-1}$), tunneling 20 \AA through water is at least 100 times slower than tunneling through protein or hydrocarbon bridges. Exclusion of water from the space between redox centers is a key factor in maximizing the efficiency of long-range electron transfer in biological molecules and assemblies.

1.7 Tunneling Timetables

The master tunneling timetable for Ru-modified proteins demonstrates that virtually all observed ET rates fall in a zone defined by the predicted distance decays for α helices (1.3 \AA^{-1}) and β strands (1.0 \AA^{-1}) (Figure 9). This large set of kinetics data provides compelling support for tunneling mediated by the sigma-bond framework of the protein. Measured protein ET rates that lie outside of this zone should be examined carefully for possible alternative mechanisms. The relatively large β value for water indicates that, in addition to large reorganization barriers, this ubiquitous biological solvent also imposes a large tunneling barrier to long-range ET. The poor coupling efficiency of water suggests that pathways involving interstitial water molecules in proteins may not be as effective as all-peptide pathways.

Simple theoretical models (e.g., uniform barrier, tunneling pathway) do not capture all of the critical factors that control the rates of protein ET reactions [85]. Refined pathway models are being developed that, in most cases, aim to identify the atoms most responsible for mediating **D/A** electronic couplings [59, 60, 73, 100]. With increasing levels of sophistication in both theory and experiment, new questions are emerging from the study of protein ET. The TP model was based on the static structure of a protein, but it is clear that protein structures are dynamic. How protein dynamics affect long-range couplings is an issue of great current interest [101–103]. Very long-range reactions proceed too slowly to sustain many biological transformations. Multistep tunneling processes, even with endergonic intermediate

Figure 9. Tunneling timetable for ET in Ru-modified proteins: azurin (●); cytochrome *c* (○); myoglobin (△); cytochrome *b*₅₆₂ (□); and HiPIP (◆). The solid lines illustrate the TP predictions for coupling along β strands ($\beta = 1.0 \text{ \AA}^{-1}$) and α helices ($\beta = 1.3 \text{ \AA}^{-1}$); the dashed line illustrates a 1.1 \AA^{-1} distance decay. Distance decay for electron tunneling through water is shown as a gray wedge. Estimated distance dependence for tunneling through vacuum is shown as the black wedge.

steps, can compete effectively with single-step long-range reactions [62, 84]. Long-range ET reactions via a series of real intermediates, rather than the virtual intermediates implicated in pathway models, may play important roles in many biochemical transformations [104].

2 Photosynthesis: Bacterial Reaction Center

Christopher C. Moser, Christopher C. Page, and P. Leslie Dutton

2.1 The Bioenergetic Context of Bacterial Reaction Centers

At a time when the electron transfer proteins of photosynthesis and respiration were first being teased apart, and well before any clear structural pictures of the proteins were available, Mitchell proposed a unifying chemiosmotic model of biological energy transduction for all bioenergetic membranes [1]. In this view, individual electron transfer proteins were embedded in an electrically insulating lipid membrane and designed to couple the energetically favorable transfer of electrons to the vectorial movement of protons across this membrane. It is now well established that the transmembrane electric field and proton concentration gradient generate a delocalized energy source which power other membrane proteins, such as the ATPase, which couples the movement of protons back across the membrane to the phosphorylation of ADP to ATP. The development of a relatively high concentration of ATP over ADP provides the principal soluble energy source for coupled chemistry in all parts of the cell.

Figure 1 shows a modern realization of Mitchell's picture in which the various electron transfer proteins and their redox centers are drawn schematically, but informed by the considerable structural information that has become available through X-ray crystallography. At the top, the reaction center proteins of bacteria represented by *Rhodobacter sphaeroides* and *Rhodospseudomonas viridis* for which high-resolution structures are available, and the reaction centers of the chloroplast membranes Photosystem I and II, all absorb light and separate charge across the membrane while generating oxidants and reductants. At the bottom, respiratory proteins represented by those found in mitochondrial membranes (similar to a range of counterparts in many bacterial membranes), guide electrons from reductant sources to oxidant sinks. The basic design links NADH to O₂ by chains of electron transfer centers within the protein complexes which are in turn inter-connected by the diffusible redox carriers cytochrome *c* and ubiquinone (Q).

Because Q is membrane-soluble and couples protons to electrons upon oxidation and reduction, it has a dominant role in chemiosmotic energy conversion. The re-

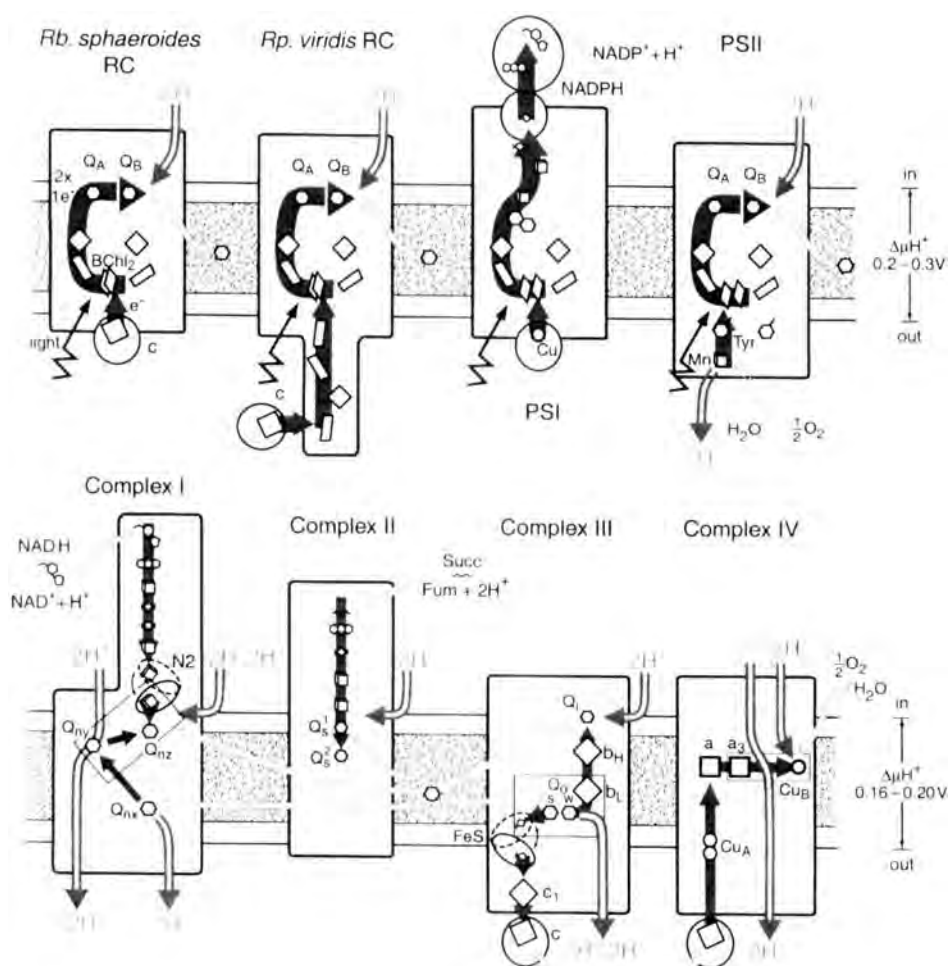

Figure 1. The major transmembrane photosynthetic reaction centers (RC) (top) and respiratory complexes (bottom) are composed of light (zigzag) activated chains (dark gray) of redox centers (open polygons) that create a transmembrane electric field and move protons (double arrows) to create a transmembrane proton gradient, fulfilling the requirements of Mitchell's chemiosmotic hypothesis. Diffusing substrates include ubiquinone (hexagon) and other sources of oxidants and reductants. PSI and PSII, photosystems I and II, respectively.

duction of Q with proton binding on one side of the membrane, followed by oxidation of QH_2 with proton release on the other side of the membrane, and the return of the neutral Q provides the basic and simplest chemiosmotic mechanism. Indeed, much of the form of the respiratory system can be understood in the simple terms of providing chains of redox centers to bring electrons to and from sites of quinone binding and oxidation/reduction. Nature has derived a means to wring extra efficiency out of Q oxidation and reduction by bifurcating electron transfer at

certain quinone binding sites, which leads to circulating eddies in the overall flow of electrons. Thus, at the Q_o binding site of Complex III (cytochrome bc_1 complex), one electron of the pair carried by QH_2 is delivered via a high potential chain to cytochrome c , while the other is carried by a low potential chain back across the membrane to Q_i . This eddy was first observed by Chance [2] (at about the same time as Mitchell was formulating his hypothesis), when introduction of an oxidant (via cytochrome c) induced a puzzling reduction of cytochrome b . We believe an analogous reductant-induced oxidation is also part of the design of the still unclear mechanism of Complex I [3].

Photosynthetic reaction centers plug into the chemiosmotic scheme by using light-excited states to create both an oxidant and a reductant. For the purple bacterial reaction centers, these oxidants and reductants are the redox carriers already described, oxidized cytochrome c and reduced ubiquinone QH_2 . Thus, in combination with Complex III, light drives a relatively straightforward cyclic electron transfer that generates a transmembrane electric field and proton gradient.

The photosystems of cyanobacteria and plants are more complicated. Photosystem I (PSI) reduces the soluble redox carrier protein ferredoxin that in turn generates NAD(P)H by ferredoxin/NAD(P) oxidoreductase. PSI also generates oxidized plastocyanin, a functional analogue of cytochrome c . Light activation of Photosystem II (PSII) leads to reduction of Q , as in the purple photosynthetic bacteria, but also to the oxidation of water to O_2 , which accumulates as a waste product in the atmosphere in what is essentially noncyclic electron flow. This waste product, of course, is what allows the essentially linear mitochondrial respiratory system in our own cells to continue to operate. The oxidized plastocyanin and QH_2 are substrate to a plant version of the mitochondrial complex III, the cytochrome b_6f complex. Thus, like the mitochondrial complexes, PSII, cytochrome b_6f and PSI are linked in a linear electron transfer chain to generate an electrochemical protein gradient. In a less clearly understood sequence PSI can apparently also participate in cyclic electron transfer via ferredoxin, which through a series of intermediate proteins leads to the reduction of membrane Q . Electrons from Q then apparently complete the cycle by oxidizing plastocyanin through the cytochrome b_6f complex.

The most basic design requirements of the bacterial photosynthetic reaction centers then, are a light energy absorbing center and two chains of redox centers that connect this light-activatable center to cytochrome c and quinone on opposite sides of the membrane. The physical process by which electrons are transferred between members of the chains in reaction centers, and indeed in the vast majority of electron transfer proteins, was also revealed by Chance, together with Devault, in these same years [4].

2.2 Tunneling Revealed in Photosynthesis

Devault and Chance [4] found that the light activation of chlorophyll in the membranes of the photosynthetic bacterium *Chromatium vinosum* which led to oxidation

Figure 2. Electron transfer kinetics of cytochrome *c* oxidation in *Chromatium vinosum* [4] and *Rhodospseudomonas viridis* [16] display temperature independence at low temperature, a herald of tunneling. The early *Chromatium* data were analyzed as a single phase, while the *Rp. viridis* data were analyzed into three phases, dominated by very fast (VF) and fast (F) phases at high temperatures, and dominated by slow (S) phase at low temperatures.

of a heme, would continue when the membranes were frozen and chilled even down to liquid helium temperatures (Figure 2). Near room temperature there was a strong Arrhenius-like dependence of the rate on temperature, but below 100 K, the rate maintained a nearly temperature-independent value. They recognized that this non-Arrhenius temperature independence meant that the slow electron transfer was not proceeding over a thermally activated barrier, but directly through the barrier—the hallmark of electron tunneling.

In tunneling, the wavefunction of the electron on a heme donor can penetrate the insulating barrier and overlap to a small but finite extent with the wavefunction of the electron on the acceptor. The greater the overlap (the lower the barrier or the closer the centers), the greater the speed that the electron tunnels from donor to acceptor. Making a host of reasonable assumptions, Devault and Chance estimated an electron transfer distance of about 30 Å. A great many theories have been applied to this single experiment, which continues to be a useful way to examine all the factors which can control the rate of electron tunneling in proteins [5].

2.3 Basic Electron Tunneling Theory

Traditionally, analysis of biological tunneling between independent redox centers that are well separated in space begins with nonadiabatic electron tunneling theory [5] and Fermi's Golden Rule in which the electron tunneling rate, k_{et} , is the product of two terms: and electronic coupling term, V_R^2 , and a nuclear term, here represented by FC for Franck–Condon weighted density of states.

$$k_{et} = \frac{2\pi}{\hbar} V_R^2 FC \quad (1)$$

2.3.1 The V_R^2 Term

The simplest view of electron tunneling begins with a uniform barrier in which the tunneling rate is expected to depend approximately exponentially on distance.

$$k_{et} \propto e^{-\beta R} \quad (2)$$

The coefficient in the exponent, β , is a reflection of the barrier height. We naturally expect that the barrier will be lower and tunneling faster if the donor and acceptor are relatively directly connected by a covalent bridge. The tunneling electron will find the regions near these atomic nuclei and bonded regions between nuclei a more energetically favorable place to be relative to the more vacuum-like regions away from these atoms. Indeed, tunneling rates do appear to fall off approximately exponentially with distance for a variety of rigidly bridged covalently linked donors and acceptors. The β value for such bridges is around 0.9 \AA^{-1} [6, 7]. This would correspond, in this simple view, to a barrier height of about 0.8 eV.

The value of β in a vacuum will depend on how much energy is required to pull an electron off the redox center. For many typical biological redox centers in isolation, this will be around 8 eV, leading to an expected β around 2.8 \AA^{-1} . β in a protein falls in between, with a value of about 1.4 \AA^{-1} [6], corresponding to an effective barrier height of about 2 eV. This β value is found to correspond to an average of the bonded and vacuum β weighted according to the average volume of a protein structure within and without the van der Waals radius of atoms [8]. Protein regions that are better packed than average appear to have a β smaller than 1.4 \AA^{-1} , while those more loosely packed appear to have a larger β . Nevertheless, a survey of electron transfer proteins with available structures shows that the standard deviation for the packing is relatively small, leading to a β range in protein of about $1.4 \pm 0.2 \text{ \AA}^{-1}$.

Furthermore, there is no statistically significant correlation of β with the productivity or wastefulness of a biological electron transfer reaction (Figure 3) [6]. Nature does not select the structure of the intervening protein medium to guide productive electron transfer and hinder unproductive electron transfer. Part of the reason can be seen in Figure 3. Although changes in β can have a profound effect on rates at long distances, changes in the biologically relevant range of 4 to 14 \AA will tend to be an order of magnitude or less. Apparently, making adjustments in the protein medium to enhance packing between redox centers is harder, given all the other roles that the protein medium must play, than maintaining proximity between redox partners. Moving redox centers closer by just 1.7 \AA leads to an order of magnitude increase in the tunneling rate.

2.3.2 The FC Term

In Fermi's Golden Rule, FC represents the Franck–Condon weighted density of states. A Franck–Condon formulation is used because the more massive atomic nuclei remain in the same position as the relatively light electron tunnels from the

Figure 3. Electron tunneling falls off exponentially with the edge-to-edge distance between redox centers with a slope (β) that depends on the barrier height. The free energy optimized tunneling rate for productive (\bullet) and unproductive (\circ) electron transfers in photosynthetic reaction centers both lie near a $\beta = 1.4 \text{ \AA}^{-1}$, suggesting an effective barrier height near 2 eV. The barrier height for covalently bridged centers is smaller ($\beta \sim 0.9 \text{ \AA}^{-1}$ or 0.8 eV), while that expected for vacuum is larger ($\beta \sim 2.8 \text{ \AA}^{-1}$ or 8 eV). The β in protein can be viewed as an average of the β for atoms and vacuum reflecting the packing density (ρ) of atoms between the redox centers. The distance range for physiologically productive reactions is 4 to 14 \AA (vertical shading).

donor to acceptor. In addition, the electron must move from a donor state to an acceptor state of the same energy.

There are a number of ways to describe this FC term. An early way of describing the nuclear position and free energy-dependent FC term was proposed in Nobel prize-winning work by Marcus [9, 10]. Marcus approximated the reactant and product, before and after electron transfer, as simple harmonic oscillators with intersecting parabolic potential surfaces. As the driving force of the reaction increases and the product potential surface drops further down in energy, the barrier that must be crossed in going from the bottom of the reactant parabola to the bottom of

the product parabola initially gets smaller and smaller. Eventually, the two parabolas intersect at the bottom of the reactant parabola and there is no barrier. The electron transfer rate in this Marcus view has a Gaussian dependence on the free energy, with a maximum rate at the mean free energy, where the optimal driving force defines the reorganization energy λ . Counter-intuitively, after increasing the driving force to where the electron transfer rate reaches a maximum ($\lambda = -\Delta G$), overdriving the reaction actually slows the rate of electron transfer down (the Marcus inverted region).

Despite its utility at room temperature, simple Marcus theory cannot explain the DeVault and Chance experiment. All Marcus reactions have a conspicuous temperature dependence except in the region close to where $\Delta G = -\lambda$. Marcus theory does not predict that a temperature-dependent reaction will shift to a temperature-independent reaction as the temperature is lowered. Hopfield proposed a quantum enhancement of Marcus theory that would permit the behavior seen in the experiment [11]. He introduced a characteristic frequency of vibration ($\hbar\omega$) that is coupled to electron transfer, in other words, a vibration that distorts the nuclei of the reactant to resemble the product state. This quantum expression includes a hyperbolic cotangent (Coth) term that resembles the Marcus expression at higher temperatures, but becomes essentially temperature independent at lower temperatures. Other quantized expressions, such as a full quantum mechanical simple harmonic oscillator behavior [12] and that of Jortner [13], give analogous temperature behavior.

2.3.3 An Empirical Tunneling Expression with Quantized FC

The electron transfer reactions in the *Rb. sphaeroides* and *Rp. viridis* bacterial reaction centers have been extensively manipulated and measured. The structure, and hence distances between redox cofactors, are known. The free energy of many reactions have been modified systematically by either cofactor substitution or amino acid replacement, so that the free energy optimized rate can be estimated with some accuracy. Furthermore, a number of these reactions have also been studied as a function of temperature, revealing a more gentle temperature dependence than that predicted by simple Marcus theory. Thus, independent of the DeVault and Chance observations, we have a reason to use a quantized FC expression. To adopt a Hopfield-like FC expression, we need to choose an $\hbar\omega$, which is a difficult parameter to define experimentally. Nevertheless, a value somewhere around 0.05 to 0.07 eV seems appropriate for several biological reactions to give to following biological tunneling rate estimate [14]:

$$\log k_{et}^{exer} = 15 - 0.6R - 3.1(\Delta G + \lambda)^2/\lambda \quad (3)$$

In this expression, the rate is in units of s^{-1} , the edge-to-edge distance in Å, and the free energy ΔG and reorganization energy λ in units of eV. This room temperature expression is simple enough that it allows quick mental order of magnitude estimates of tunneling rates and often allows a prediction of the electron tunneling rate

for an unknown reaction, or an assessment of whether an observed rate is a tunneling rate or rate limited by some other, nontunneling reaction.

If the packing density (ρ) between redox cofactors is known (i.e., the fractional volume of the medium between the cofactors that is within the van der Waals radius of protein atoms), the value of β can be adjusted to reflect a higher or lower effective barrier to electron tunneling to improve the rate estimate [8]:

$$\log k_{et}^{exer} = 13 - (1.2 - 0.8\rho)(R - 3.6) - 3.1(\Delta G + \lambda)^2/\lambda \quad (4)$$

To extend this expression to any temperature means that we have to include an explicit $\hbar\omega$, the Boltzman constant k_B and absolute temperature (T) in the final Gaussian term for the Franck–Condon factor. The resulting expression is harder to solve in one's head, but can be useful.

$$\begin{aligned} \log k_{et}^{exer} = 13 - (1.2 - 0.8\rho)(R - 3.6) \\ - 0.22(\Delta G + \lambda)^2/(\lambda\hbar\omega\text{Coth}[\hbar\omega/2k_BT]) \end{aligned} \quad (5)$$

2.4 Devault and Chance's Prediction

Devault and Chance made rough estimates of some of the basic theoretical parameters and arrived at a predicted tunneling distance of about 30 Å. Subsequent resolution of the analogous RC structure in *Rp. viridis* [15] showed the heme to bacteriochlorophyll dimer (BChl₂) distance to be substantially correct, but in an unexpected way. The RC contained not one heme but four arranged in a near line extending away from the BChl₂ (Figure 4). We label these hemes Heme1, Heme2, etc. in order of distance from the BChl₂, although they are often known by their reduced alpha-band absorption maxima. As Devault and Chance lowered the temperature, the dominant heme that was oxidized by BChl₂⁺ shifted from the nearby Heme1 (*c*₅₅₉) to the low potential Heme2 (*c*₅₅₂). Even the more distant Heme3 (*c*₅₅₆) can be seen to participate in electron transfer in *Rp. viridis*.

The low-temperature kinetics data of these early difficult experiments did not have the time or spectral resolution to consider these possibilities. However, there is now an excellent set of temperature-dependent kinetics data for the similar bacterium *Rp. viridis* [16, 17]. These data clearly show multiphasic kinetics that can be resolved into very fast, fast and slow phases, most of which slow with temperature roughly an order of magnitude before reaching a temperature-independent plateau. What does change dramatically with temperature is the contribution of each of these phases, with the fast phases falling away dramatically at a temperature around 210 K for the wild-type *Rp. viridis*. Thus, the overall result is a dramatic decrease in half-time of the reaction with temperature, as Devault and Chance observed.

Several obvious questions are presented by this reinterpretation of the pioneering Devault and Chance experiments. First, why does Heme1 stop functioning as the

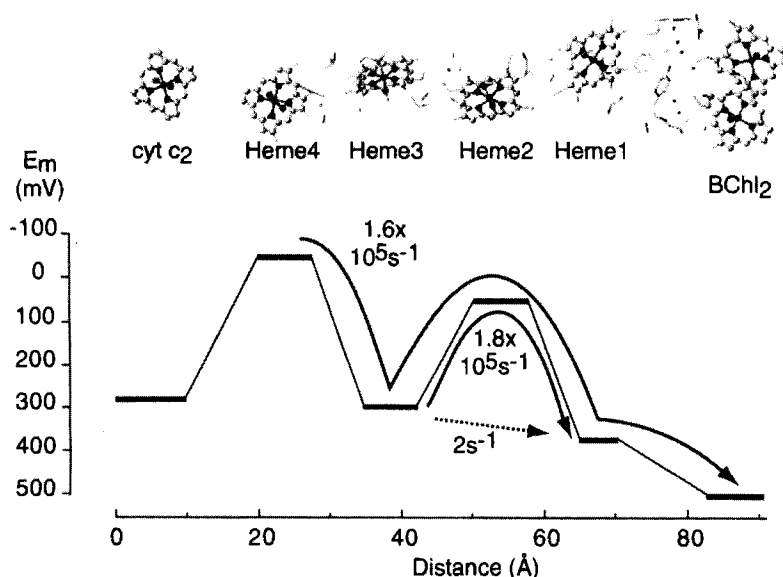

Figure 4. Electron transfer along the chain of *c* hemes in *Rhodospseudomonas viridis* is physiologically rapid, despite the more than 80 Å traversed through a series of endergonic and exergonic tunneling reactions. Rates from Heme4 to BChl_2^+ (solid curve) and rates from Heme3 directly to Heme1 (dashed line) or through Heme2 (solid curve) are calculated using the equations in the text.

temperature is lowered? It appears that the midpoint potential of Heme1 and BChl_2 are quite close. In the analogous *Rp. viridis*, the functional redox midpoint potentials (E_m) are even closer than the redox titration equilibrium values [17, 18] as the charges on the various hemes exert an electrostatic influence on one another. In whole cells, the transmembrane electric field seems to make the acting potential difference between BChl_2 and Heme1 even smaller [19]. The driving force for the reaction is apparently so small that changes in the environment (such as rearrangement of nearby water molecules) can make the driving force unfavorable on freezing, and eliminate the fast phase of the reaction.

What would happen if Heme1 did not freeze out? Mutants have been created in which the relatively fast ~ 200 -ns Heme1 oxidation does not freeze out and remains relatively temperature-insensitive down to cryogenic helium temperatures [20]. Thus, Hopfield's original reason for proposing a quantized Marcus expression in order to get a smooth transition over three orders of magnitudes between the temperature-dependent and temperature-independent regions appears to have been removed. Incidentally, these same mutants, together with their crystal structures and midpoint potential measurements [21], clearly show that numerous changes of an amino acid directly between Heme1 and BChl_2 (and presumably on any electron transfer "pathway" that might be drawn between them) have little effect on the electron tunneling rate. The changes that are observed can be easily understood in terms of small changes in distance, free energy, and packing. The wild-type amino

acid is not even the fastest and by no means “optimized” as a naïve view of natural selection might suggest.

If the dominant electron transfer at low temperature is from the considerably more distant Heme2 (24.6 Å), why is the rate as fast as a millisecond and not the 10- to 100-ms timescale typical for these distances, packing densities and driving forces (Eq. 3)? Furthermore, at moderate potentials when Heme1 and Heme3 are reduced but the much lower potential Heme2 in between is oxidized, how can Heme3 reduce photo-oxidized Heme1? To address these questions we need to look into the role of electron transfer chains in biological systems.

2.5 The Design of Natural Electron Transfer Chains

Chains of redox cofactors are commonly used to guide electron transfer through protein complexes and to and from catalytic sites. Many examples can be seen in Figure 1. The natural robust design of electron transfer proteins places redox centers close enough that the tunneling rates through the chains are rapid compared to the timescale of the catalytic turnover of the enzyme [8]. Thus, there is little selective pressure to have the redox potentials of members in a chain step evenly from low potential to high potential along the chain. Indeed, redox potentials can vary rather wildly up and down, as long as the overall electron transfer through the chain is modestly favorable. There are many examples from photosynthetic and respiratory redox chains and from enzymes [8].

To extend the empirical tunneling expressions above to consider endergonic reactions, we can assume for simplicity that the forward and reverse electron transfers can be related by a temperature and Boltzman constant-dependent equilibrium constant.

$$\log k_{et}^{ender} = \log k_{et}^{exer} - (\Delta G/RT) \log e \quad (6)$$

At room temperature, the $-(\Delta G/RT) \log e$ term slows the reaction by an order of magnitude for every approximately 60 mV. Although this equation may be conveniently used to provide a rate estimate for endergonic electron transfer, the equation may not always be a good approximation for reactions in which both the forward and reverse reactions are rate-limited by tunneling. Instead, the ratio of the forward and reverse reaction rates may be temperature-independent, as has been demonstrated in Tutton salts [22]. In this case it may be best simply to extend the exergonic equation into the endergonic region.

2.5.1 The High Potential Redox Cofactor Chain in *Rp. viridis*

The use of electron transfer chains enables living systems to transfer electrons rapidly between widely separated components, when transfer would be impossibly

slow by direct electron tunneling. Using the above equations, electron transfer from cytochrome c_2 interfacing with Heme4 of the *Rp. viridis* chain can reduce $\text{BChl}_2^+ \sim 60 \text{ \AA}$ away at the other end of the chain at $\sim 10^4 \text{ s}^{-1}$, compared to the direct tunneling rate which would take longer than the age of the universe. This is achieved despite the fact that the midpoint potentials of the intervening hemes are highly nonoptimized for this reaction: the electron has to scale two endergonic steps that are each more than 300 mV uphill. Nevertheless, the proximity of the redox centers in the chains allows this to be achieved robustly. Indeed, simulations indicate that long-distance electron transfer through the c heme chain would proceed at physiologically appropriate rates even after relatively dramatic changes in the zigzag potential profile found in the natural chain (Figure 5).

The situation is different at nonbiological cryogenic temperatures however. Consider the reaction from Heme3 to Heme1 and BChl_2^+ , which takes place in about 2 μs and represents up to one-third of the total heme oxidation after a single flash at room temperature in whole cells [19]. The reorganization energies for these reactions are not well measured, but we can make rate estimates using typical reorganization energies of around 0.7 to 0.8 eV. At room temperature, using Eq. 3, direct electron tunneling from Heme3 to Heme1 over 21.5 \AA is far too slow at 2 s^{-1} . Endergonic electron transfer from Heme3 to Heme2 over 8.1 \AA would be 40 μs , while the reverse exergonic reaction would be about 0.4 ns. Electron tunneling from Heme2 to Heme1 over 7.0 \AA would be about 50 ps. The overall solution of these coupled rates gives a room temperature characteristic time of Heme3 to Heme1 electron transfer of about 6 μs ; close to the observed value of 1.7 μs [17, 23–25]. Indeed, if the reported electrostatic coupling between oxidized Heme1 and Heme3 were to raise the nonequilibrium E_m of Heme2 by only 30 mV, the calculated and observed rates would be the same. At 245 K the exergonic rate from Heme2 to Heme1 will slow slightly (assuming a characteristic frequency of about 0.05 eV and a Gaussian FC expression akin to Hopfield [11]). But the endergonic rate from Heme3 to Heme2 will slow by a factor of 2.6 just because of the Boltzman term alone. Ortega and Mathis report a slowing from 1.7 μs to 6.3 μs , a factor of 3.7, entirely in line with the calculated value [17]. However, at cryogenic helium temperatures the endergonic rate penalty predicted from Eq. 6 would be too severe to allow rapid endergonic Heme3 to Heme2 to Heme1 electron tunneling. Now the direct Heme3 to Heme1 rate would dominate, with a calculated rate around 1 s^{-1} . This is difficult to observe experimentally in wild-type, however, because the low-temperature rise in Heme1 E_m removes it from participation at these temperatures.

On the other hand, the low-temperature tunneling from Heme2 to BChl_2 can be observed. At an edge-to-edge distance of about 24.6 \AA , even with a slightly better than average packing of 78 %, the half-time of tunneling at low temperature will be about 10 to 100 ms, depending on the choice of reorganization energy and the characteristic frequency $\hbar\omega$. This is significantly slower than the 1–2 ms observed rate (Figure 2). This suggests that when the Heme1 cofactor is prevented from its natural thermally activated participation, it falls back to the role of lowering the barrier for electron tunneling. A rise in the average packing from 78 % to 88 % would accelerate the tunneling rate to observed low-temperature values. Since Heme1 occupies roughly one-third of the distance span between Heme2 and BChl_2 ,

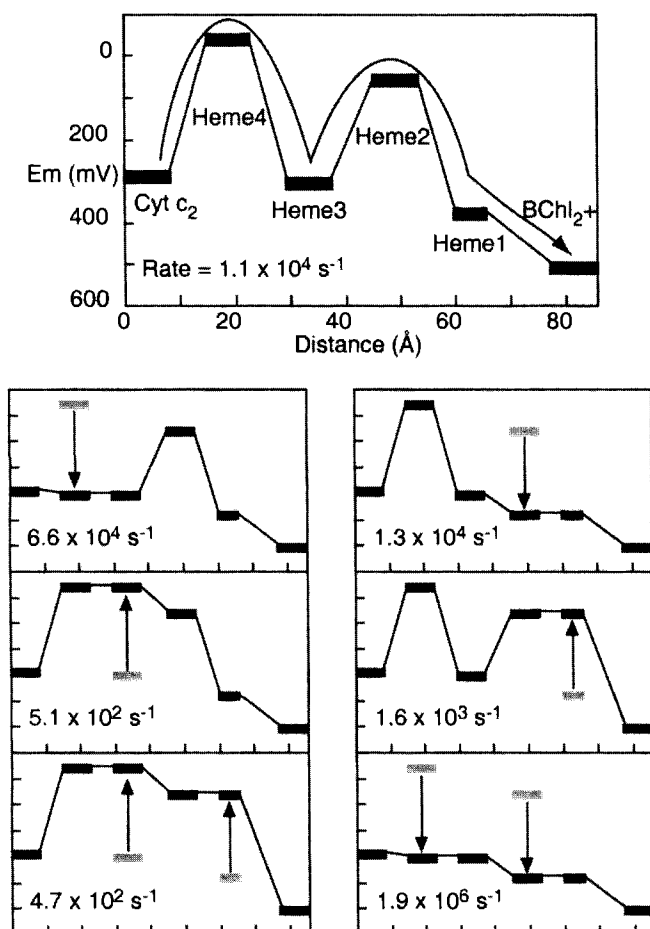

Figure 5. The robustness of long-distance electron transfer through the cytochrome *c* heme chain in *Rhodospseudomonas viridis* is apparent from the relative insensitivity to extensive changes in the redox midpoint potentials of the individual hemes along the chain. Using the equations described in the text, most cytochrome *c*₂ to BChl₂⁺ rates remain physiologically rapid as the zigzag potential profile is changed.

a β for the reduced Heme1 atoms of about $0.5\text{--}0.6 \text{ \AA}^{-1}$ (as opposed 0.9 \AA^{-1} for amino acid atoms) for an effective barrier height of about 0.3 eV would accomplish the appropriate rate acceleration.

While intervening but electrochemically incompetent hemes may lower the tunneling barrier compared to protein at cryogenic temperatures, we do not support a view in which heme-to-heme electron transfer is generally considered to be from iron center to center (13.9 \AA between Heme2 to Heme1 and 16.1 \AA between Heme1 and BChl₂) with a special β for electron transfer through the heme of 0.6 \AA^{-1} . Indeed, our preference for using macrocycle edge-to-edge distances in our tunneling

calculations comes from the success of this method in the majority of rate predictions in multiheme systems, including the *Rp. viridis* heme chain.

By distinguishing the intervening heme cofactor from the amino acid tunneling medium, we have a picture that resembles superexchange. Some apparently prefer to introduce a superexchange reaction rather than contemplate a significantly endergonic intermediate reaction, even at room temperature [26, 27]. In superexchange, electron transfer from donor to acceptor occurs in a single-step coherent mechanism that uses the intermediate redox center only as a virtual intermediate (although in this case the virtual intermediate would correspond to putting an extra electron on a heme that was already reduced). The rate of this tunneling mechanism is dependent on the electronic coupling of the donor and acceptor with this virtual intermediate and the energy gap between the real donor and acceptor states and the virtual intermediate state. Generally, superexchange through an intermediate protein redox center requires an unusually strong electronic coupling between redox centers. This is hard to achieve for redox centers separated by several angstroms. However, when the redox centers are within 5 Å, then endergonic electron transfer becomes a competing mechanism. There is no clear evidence of cofactor superexchange as a tunneling mechanism at physiological temperatures (although superexchange can become reasonable at cryogenic temperatures), and hence no clear evidence that natural selection exploits cofactor superexchange in the design of electron transfer systems.

2.5.2 The Low-Potential Chain in *Rp. viridis* and *Rb. sphaeroides*

By focusing on the DeVault and Chance observations, we have concentrated on describing the engineering of the donor side of the photosynthetic reaction centers. A redox chain is also responsible for the transfer of an electron from the excited BChl₂ to the ubiquinone acceptor on the low-potential side of the reaction center. While the overall engineering time constraint on the donor side is the typical micro- to millisecond time scale of most enzymatic k_{cat} values and intraprotein electron transfers in Mitchell's chemiosmotic system, the acceptor side faces the much more severe time constraint of the typically nanosecond decay rate of excited states. Thus, the initial photosynthetic charge separation after light excitation of the BChl₂ relies on even more closely spaced redox components and avoids large endergonic electron transfer reactions as the electron is guided to monomer BChl and bacteriopheophytin (BPh) on a timescale of 3 ps.

Reaction center design hits a relatively weak link at this point. The electron on BPh has several possible acceptors: the physiologically productive Q_A (10.0 Å distant and 0.6 eV in driving force in *Rb. sphaeroides*), and several physiologically unproductive reactions, including unproductive charge recombination by direct electron transfer between BPh⁻ and ground-state BChl₂⁺, which takes place over nearly the same distance as BPh⁻ to Q_A; equally unproductive back electron transfer through nearby BChl to BChl₂^{*} followed by radiative decay; as well as electron transfer to other redox centers such as the "inactive" BPh on the M side of the reaction center protein (16.5 Å and probably slightly endergonic). Of the 1.4 eV

of overall driving force delivered by the photon to BChl₂, relatively little (~ 0.2 eV) is consumed upon reducing BPh; however, reduction of Q_A by BPh expends about half of this energy. This assures that the FC factor for this reaction will be nearly optimal at about 200 ps. The similar distance BPh⁻ to ground state BChl₂⁺ has nearly 1.2 eV of driving force, and therefore should be within an inverted region of the Marcus relationship with a suboptimal FC factor. Under these conditions physiologically productive electron transfer takes place with 99 % efficiency.

However, if the distance between BPh and Q_A were just a few angstroms longer, or if the driving force of this reaction was several tenths of an eV larger or smaller, then the quantum efficiency of the reaction center would suffer as charge recombination became more common. On the other hand, if the driving force for the BPh⁻ to BChl₂⁺ ground-state reaction were *decreased*, then this inverted region reaction would accelerate and also lower the efficiency of productive charge separation. Experiments with reaction centers oriented in an external electric field provide some evidence that this is the case [28]. Moreover, shortening the distance between redox centers—usually a method of increasing robustness in electron transfer protein design—does not improve the robustness of this step in photosynthesis. Shortening this distance would indeed make BPh to Q_A electron transfer faster than BPh to BChl₂⁺ electron transfer, but at the cost of speeding up the reverse, Q_A⁻ to BChl₂⁺ electron transfer. The relatively long time that the electron resides on Q_A (microseconds) before electron transfer to Q_B means that this reverse endergonic reaction can become significant.

The near mirror symmetry of the low-potential chain components places BChl and BPh redox components on the M or “B” side of the reaction center, where they could interfere with normal charge separation. Using the tunneling equations described, the electron transfer rates between any and all of the redox centers in the reaction center can be simulated. The excited BChl₂^{*} is presented with two BChl monomers to accept the electron. Simply by lowering the M-side BChl monomer redox potential more than 100 meV below the BChl₂^{*} (see [29]) or significantly raising the reorganization energy of this M-side reaction to a more typical 0.5 to 0.7 eV, slows the wrong side rate sufficiently to avoid these unproductive reactions. If the wrong side BPh were to become reduced, it is always possible to have BPh to BPh electron transfer across the symmetry axis of the reaction center. However, at a distance of 16.5 Å, this low driving force reaction at about 0.3 ms will compete unfavorably with charge recombination to BChl₂⁺ unless it has been previously reduced by the *c* heme chain.

It appears that the blunt tool of natural selection has encouraged the proliferation of natural electron transfer proteins that are robust and can suffer the insults of mutation and genetic changes while still preserving significant function, and has removed designs that may be highly optimized but fragile. For the reaction center, dimerization has duplicated the low-potential chain of redox cofactors, but productive directional electron transfer down one branch appears to be relatively easily accomplished by mutations that break the symmetry and impose unfavorable Franck–Condon factors on the disfavored side. Electron transfer from the chlorins to the quinones seems to be a relatively clumsy reaction that maintains the high quantum efficiency of the reaction center at the price of consuming a large driving

force, which robs charge separation of some of its overall redox engineering efficiency. It may be that the robust function in *C. vinosum*—and especially in *Rp. viridis* where the long-wavelength-absorbing chlorophylls b make the chlorin to quinone energy gap relatively small—is assured by a counterbalancing highly robust high-potential heme chain, which fills the hole on BChl_2^+ to prevent wasteful back-reactions. This robustness, of course is one of the reasons that DeVault and Chance were able to make their ground-breaking observations more than three decades ago.

3 Respiration: Cytochrome Oxidase

Bo G. Malmström

3.1 Introduction

Living organisms are chemical machines and, like all machines, are driven by energy. Ultimately, this energy is derived from the sun, the solar energy being captured in the processes of photosynthesis (see Volume III, Part 1, Chapters 1, 2). The immediate energy demand of all living cells is, however, satisfied by the breakdown of foodstuffs, which is coupled to the synthesis of ATP, the universal energy-storage molecule in living cells. In anaerobic organisms a limited amount of ATP is formed in the reactions of glycolysis, with the concomitant formation of NADH, the reduced form of the coenzyme of the oxidative enzymes of the glycolytic system. In aerobic organisms, from bacteria to humans, on the other hand, much more energy is derived from the oxidation of this NADH by molecular oxygen. This occurs in the respiratory chain, a series of electron transfer (ET) complexes firmly bound to the inner mitochondrial membrane in eukaryotes, or to the plasma membrane in bacteria. The ET complexes of the respiratory chain are shown in Figure 1, together with the ATP synthase. The ET reactions in these complexes—the names of which are given in the figure—are coupled to the translocation of protons from one side of the membrane to the other, and the electrochemical potential thus created is used to drive the synthesis of ATP in the ATP synthase complex, according to the chemiosmotic principle of Mitchell [1].

The terminal component of the respiratory chain is cytochrome *c* oxidase, which reduces dioxygen to two molecules of water. This cytochrome was discovered as the *Atmungsferment* by Warburg already in the 1920s and shown by him to be a heme protein in 1929 [2], an achievement for which he was awarded the Nobel Prize for Physiology or Medicine in 1931. The electron donor of the oxidase, cytochrome *c*, had been found earlier by Keilin (see [3]), as had one of the oxidase heme components, cytochrome *a*, whereas Keilin did not observe the dioxygen-reacting cytochrome *a*₃ until 1939. Keilin had before this discovery maintained that the oxidase is not a heme but a copper enzyme, and we now know that it also contains two

Figure 1. The respiratory chain of mitochondria.

copper sites, Cu_A and Cu_B (see [4] for recent reviews on cytochrome oxidase structure and function). The redox centers of the oxidase are $>10 \text{ \AA}$ apart, except for cytochrome *a*₃ and Cu_B, which form a bimetallic unit, and the focus of this chapter will be the intramolecular ET reactions between these centers and their coupling to proton transfer.

3.2 Structure of Cytochrome Oxidase

For a long time, research on long-range ET in the respiratory chain and other membrane-bound systems was severely hampered by the lack of detailed structural information. The first such system for which a high-resolution X-ray structure became available was a bacterial photosynthetic reaction center, determined by Deisenhofer et al. in 1985 [5], and this resulted in these investigators receiving a Nobel Prize for Chemistry in 1988. Michel and collaborators then attempted to obtain crystals of a bacterial cytochrome oxidase, and they published the structure of *Paracoccus* oxidase in *Nature* on 24 August 1995 [6]. A day later, the structure of bovine heart cytochrome oxidase was described in *Science* by the Yoshikawa group in Japan [7]. The structures of the three heaviest subunits of the bovine oxidase, which are remarkably similar to their bacterial counterparts, as well as the location of the cytochrome *c* binding site, are illustrated in Figure 2 (left). As can be seen, the redox centers are bound to the two heaviest of the three subunits, Cu_A in subunit II and cytochrome *a* as well as cytochrome *a*₃-Cu_B in subunit I. The spatial relationship between the redox centers is highlighted in Figure 2 (right). The two

Figure 2. The crystal structure of the three heaviest subunits of cytochrome oxidase, with the binding site for cytochrome *c* indicated (left), and of the redox centers (right). From Ref. [4a], with permission.

hemes are almost equidistant from Cu_A (22.1 Å to cytochrome *a* and 19.5 Å to cytochrome *a*₃), and the heme–heme distance is 13.2 Å.

As can be seen in Figure 2, Cu_A is a binuclear unit, a point which for a long time was a controversial issue (see [8] for reviews). This unit has a single unpaired electron, which is completely delocalized over the two Cu ions and the bridging S atoms [9]. As will be discussed later (Section 3.4.1), the binuclear, delocalized nature of this site is important for its ET properties. Cytochrome *a* is a low-spin heme with two axial His ligands from separate transmembrane helices in subunit I. Cytochrome *a*₃ has one axial His from the same helix that provides one of the cytochrome *a* ligands, whereas the other axial site is free to interact, in its reduced form, with the dioxygen molecule. In the oxidized enzyme, cytochrome *a*₃ is anti-ferromagnetically coupled to Cu_B. In the structures it was, in addition, possible to discern putative proton pathways, which will be introduced later (Sections 3.3.2 and 3.4.4).

3.3 Methods for Studying Electron Transfer in Cytochrome Oxidase

The rates of the internal ET reactions between the redox sites, as well as that in the subunit II–cytochrome *c* ET complex, are all higher than the time resolution of the stopped-flow method ($\sim 10^3$ s⁻¹), so that more rapid techniques must be used to study these reactions. Generally, photochemical techniques involving a laser flash

have been employed (see [10] for reviews). The ET kinetics has usually been followed by changes in optical absorption of the redox centers in the visible (the cytochromes) or near-infrared (Cu_A) regions, but the dioxygen-reduction sequence has also been monitored by low-temperature electron paramagnetic resonance (EPR) [11] and resonance Raman [12].

3.3.1 Electron Injection into Cytochrome Oxidase

Even if pulse radiolysis has been used [13], most studies of the initial electron entry into cytochrome oxidase are based on the finding that at low ionic strength cytochrome *c* forms a strong electrostatic complex with the oxidase [14]. Cytochrome *c* itself cannot be photoactivated, but in the complex with the enzyme it can be reduced by photochemically generated radicals, such as that of 5-diazariboflavin [15]. Another approach has been to employ a photoinduced uroporphyrin/NADH reduction system [16].

More direct ET into the oxidase has been initiated photochemically with an artificial electron donor, tris(2,2'-bipyridyl)ruthenium [17], electrostatically bound to the enzyme, and with Ru-labeled cytochrome *c* [18]. An objection to these types of experiments is, of course, that they involve unnatural electron donors, whose site of interaction with the oxidase may be different from that of cytochrome *c* itself. This objection does not apply to experiments in which the strongly reducing triplet state of bound Zn-cytochrome *c* is generated photochemically to inject an electron into the oxidase [19], since this derivative of cytochrome *c* has the same structure and has been shown to bind to the same site as the native protein [20].

The electron exchange between cytochrome *c* and the oxidase can also be studied in experiments in which the fully reduced electrostatic complex is oxidized by O_2 in a flow-flash (see Section 3.3.3) experiment [21].

3.3.2 Flash Photolysis of Mixed-Valence Carboxycytochrome Oxidase

Incubation of oxidized cytochrome oxidase under an atmosphere of CO results in the formation of the so-called mixed-valence state, a form in which the cytochrome $a_3\text{-Cu}_B$ site is reduced and has bound CO, whereas cytochrome *a* and Cu_A remain oxidized [22]. The dissociation of the bound CO by flash photolysis in the absence of O_2 induces an electron backflow from the reduced cytochrome $a_3\text{-Cu}_B$ site to the oxidized redox centers, as first discovered by Boelens et al. [23] and later confirmed by Brzezinski and Malmström [24]. These authors thought that the electron acceptor is Cu_A , but later it has been shown [25] that both cytochrome *a* and Cu_A are sequentially reduced (see Section 3.4.2). In addition, it was found that oxidation of cytochrome a_3 causes deprotonation of an acid-base group in its vicinity [26], as will be discussed further in Section 3.4.4.

One basis for the technique described is the fact that the internal ET and the proton reactions are faster than CO recombination with reduced cytochrome a_3

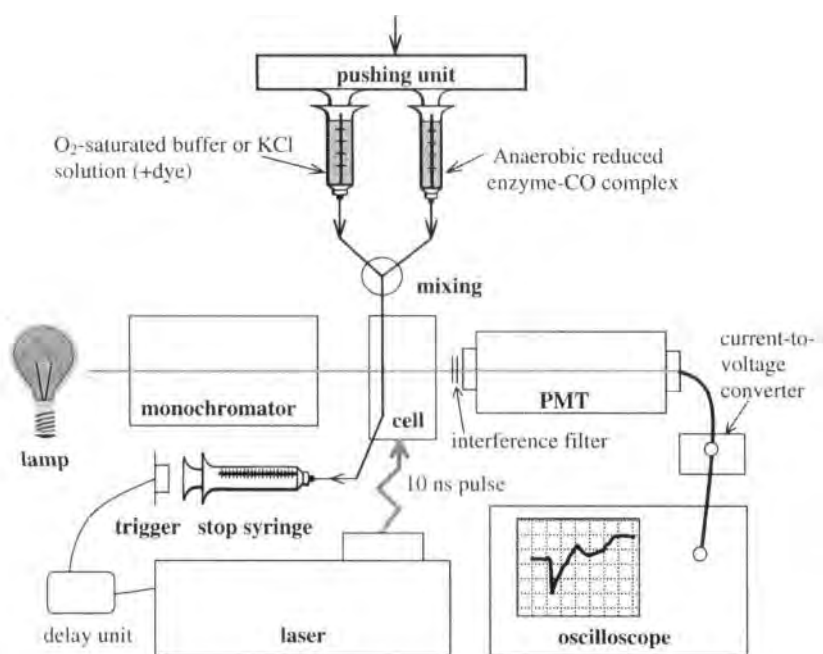

Figure 3. A flow-flash apparatus. PMT, photomultiplier tube.

[27]. The rebinding of CO shifts the ET and proton equilibria back to their original positions, which makes it possible to initiate the reactions repeatedly with a new laser flash. In this way, several kinetic traces can be averaged, which considerably improves the signal-to-noise ratio.

3.3.3 The Flow-Flash Technique: The Reduced Cytochrome Oxidase–Dioxygen Reaction

The method generally used for studying the reaction of reduced cytochrome oxidase with dioxygen is the flow-flash technique developed by Gibson and Greenwood [27a]. The experimental set-up used in the Göteborg laboratory is shown in Figure 3, and most modern flow-flash apparatus have this general design. In a flow-flash experiment, the mixed-valence enzyme or the fully reduced oxidase–CO complex is mixed with an O₂ solution in a stopped-flow apparatus. The mixing device fires a light flash after a short delay (50–200 ms), and this dissociates the bound CO and initiates the reaction with O₂, as illustrated for the fully reduced enzyme in Figure 4. The basis of the technique is the fact that O₂ binding is faster than CO recombination [27a]. The results from flow-flash experiments on ET and proton-transfer reactions involved in the reoxidation of reduced cytochrome oxidase by O₂ will be discussed in Sections 3.4.3 and 3.4.4.

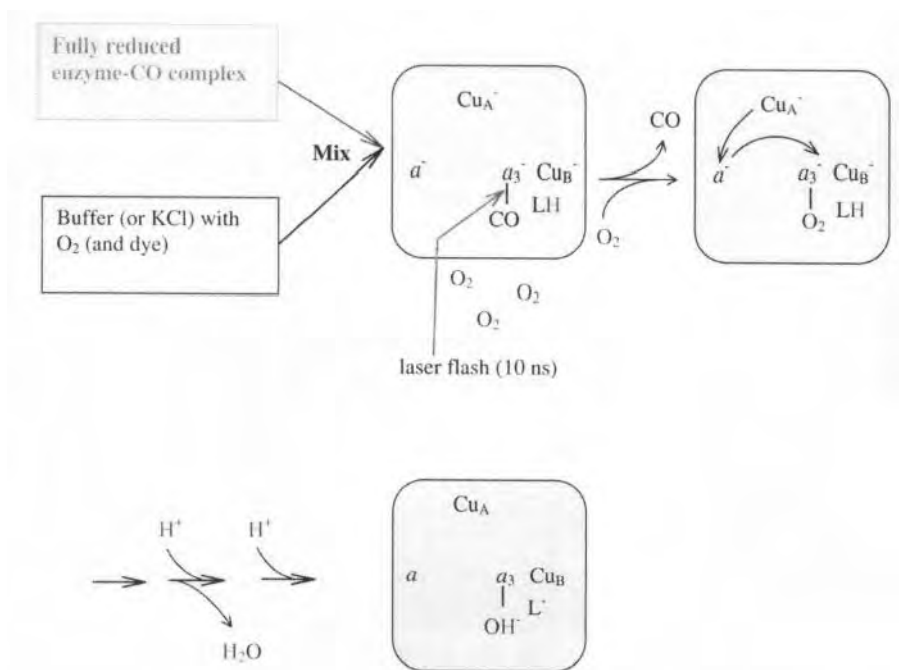

Figure 4. A flow-flash experiment with the fully reduced enzyme.

3.4 Electron Transfer Reactions in Cytochrome Oxidase

3.4.1 Reduction of the Initial Electron Acceptor

On the basis of stopped-flow experiments, it was long considered that the primary acceptor of an electron from cytochrome *c* is cytochrome *a* [27b, 28], but it was recognized early on that Cu_A is also rapidly reduced [29]. In a study of the reaction of the reduced cytochrome *c*-cytochrome oxidase complex with dioxygen, Hill concluded that Cu_A is actually the primary electron acceptor [21], and this conclusion was supported by experiments with external electron donors [15, 16a, 17], with Ru-modified cytochrome *c* [18] and with Zn-cytochrome *c* [19]. Cu_A as the primary electron acceptor could be reconciled with the earlier stopped-flow results implicating cytochrome *a*, because there was found to be a rapid redox equilibrium between Cu_A and cytochrome *a* [13, 25, 30] ($\sim 10^4$ s⁻¹; see Section 3.4.2). In addition, cytochrome *a* in the oxidized enzyme has a higher reduction potential than Cu_A [31], so that the addition of a single electron in a stopped-flow experiment results in a larger degree of reduction of cytochrome *a* compared to Cu_A.

The conclusion that Cu_A is the primary acceptor of electrons from cytochrome *c* is supported by work with small, soluble Cu_A domains, consisting of only the C-terminal, solvent-exposed portion of subunit II [32]. The Cu_A sites in these domains

can be rapidly reduced by external electron donors [33] as well as by cytochrome *c* itself [32a, 33] or by Zn-cytochrome *c* [19].

The rate of electron entry into the Cu_A site in electrostatic complexes with cytochrome oxidase has been found to be $\sim 10^5 \text{ s}^{-1}$ with an artificial electron donor [17] as well as with Ru-modified cytochrome *c* [18] or with Zn-cytochrome *c* [19]. An equally high rate was also observed with native cytochrome *c* in the experiments with the oxidation by dioxygen of the complex with the reduced oxidase [21]. Such a high rate could only be obtained at the low driving force involved ($\sim 30 \text{ meV}$), if the reorganization energy (λ) for ET is very small [34]. The fact that the rate is not even higher with Zn-cytochrome *c*, despite a 1-eV higher driving force, was attributed [19] to the reaction being in the Marcus inverted region [34]. It has been shown [35] that a small λ is a result of the mixed-valence, delocalized nature of the binuclear Cu_A site. Mutagenesis work producing a localized binuclear [36] or a mononuclear Cu site [37] has demonstrated that the unique structure of the native site is, in fact, essential for rapid reduction by cytochrome *c*.

Electron entry from cytochrome *c* into the oxidase undoubtedly involves its exposed heme edge. This is surrounded by four lysyl residues [38], which are involved in electrostatic binding to a negative patch of aspartate and glutamate residues on the extramembranous domain of subunit II, as has been demonstrated by site-directed mutagenesis [39]. One of the acidic residues (Asp178) in this negative patch is located in a loop just above one of the Cu_A ligand histidines (His181) in the structure of the *Paracoccus* oxidase [6], as can be seen in the detailed structure of the Cu_A site shown in Figure 5, and a corresponding Asp residue is also found in a number of engineered Cu_A domains [32], including two with their X-ray structures determined [40]. This suggests an obvious ET pathway from the heme of cytochrome *c* to the binuclear Cu_A site.

3.4.2 Internal Electron Transfer Reactions

Flash photolysis of the mixed-valence cytochrome oxidase–CO compound leads to a drop in the apparent reduction potential of cytochrome *a*₃, and this results in a backflow of electrons from cytochrome *a*₃ to the other redox sites. Three kinetic phases can be observed [26, 41], with relaxation rate constants (i.e., the sum of the rate constants for the forward and reverse reactions of the equilibria involved) of 3×10^5 , 2×10^4 , and $\sim 10^3 \text{ s}^{-1}$. The first two phases involve ET $a_3 \rightarrow a$ and $a \rightarrow \text{Cu}_A$, respectively; the third phase is strongly pH-dependent and represents further electron re-equilibration between *a*₃ and *a*, following the dissociation of a proton caused by the initial oxidation of *a*₃ [26, 41a], as will be further discussed in Section 3.4.4. Direct electron equilibration between *a*₃ and Cu_A is not observed.

The normal forward ET reactions in the turnover of cytochrome oxidase, $\text{Cu}_A \rightarrow a$ and $a \rightarrow a_3$, can be calculated to have rate constants of 1.2×10^4 and $2 \times 10^5 \text{ s}^{-1}$. Thus, the electron transfer steps per se may not provide any limitation on the turnover rate but rather their coupling to other reactions, such as proton transfers (Section 3.4.4) or conformational changes. The λ values associated with the two internal ET reactions have been estimated to be 0.3 and 0.76 eV, respec-

Figure 5. The Cu_A site of subunit II with the loop providing the ligands and the connection to subunit I. From Ref. [4b], with permission.

tively [41a, 42]. The first value emphasizes again (cf. Section 3.4.1) that the inner λ associated with the reduction of Cu_A must be very small; it can be noted that extended x-ray absorption fine structure (EXAFS) spectroscopic measurements have shown that the structural changes on reduction are minimal [43]. The major part of the higher value of λ for the $a \rightarrow a_3$ ET must be associated with a_3 , which may be related to the fact that the dioxygen-reducing site is available to the solvent via proton pathways (see Section 3.4.4).

The crystal structures clearly suggest pathways for electron tunneling between the redox centers of cytochrome oxidase, as illustrated in Figure 6 [44]. It may first be noted that an electron from cytochrome *c* must enter the Cu_A site from a binding

Figure 6. Part of the structure of subunits I and II showing the ET pathways. From Ref. [44], with permission.

site above the ligand His161 (see Section 3.4.1), whereas it will leave it via a pathway starting with the ligand His204 (the numbering is here that for the bovine enzyme). The necessity of different pathways for entering and leaving the initial electron acceptor may be one additional reason, besides the lowered reorganization energy (Section 3.4.1), for this being a binuclear Cu site rather than a blue copper, to which it is otherwise related; the electronic delocalization over the entire site effectively reduces the tunneling distance.

The internal ET reactions in cytochrome oxidase have recently been subjected to a detailed pathway analysis [45]. The pathway for the Cu_A → *a* ET starts with a hydrogen bond between His204 and a carbonyl group in a loop of subunit I (Figure 6). The total pathway comprises 14 covalent bonds and two H bonds, corresponding to an effective tunneling length of 25.2 Å, and an activationless rate of

$9 \times 10^5 \text{ s}^{-1}$ was estimated. As the driving force for the reaction is only 90 meV, λ must be small to achieve the experimentally observed rate of $1.2 \times 10^4 \text{ s}^{-1}$, and a value as low as 0.3 eV has been estimated, as already discussed. All potential $\text{Cu}_A \rightarrow a_3$ tunneling pathways are so long (tunneling lengths of 30.8–33.6 Å) that they would give rates several orders of magnitude lower than the rate for the $\text{Cu}_A \rightarrow a$ ET. This explains, why $\text{Cu}_A \rightarrow a_3$ ET is not observed, despite the fact that the distances from Cu_A to the two hemes differ only slightly (22.1 and 19.5 Å, respectively).

There are three almost equivalent pathways for the $a \rightarrow a_3$ ET reaction [45], all going through the ligand histidines of the two hemes (His378 and His376). The one shown in Figure 6 utilizes the single residue (Phe377) between these histidines, and it comprises 16 covalent bonds, corresponding to a tunneling length of 22.4 Å. The estimated activationless rate is $7 \times 10^6 \text{ s}^{-1}$, and a λ of 0.44 eV would give the experimentally observed relaxation rate of $3 \times 10^5 \text{ s}^{-1}$; this λ value is somewhat lower than the value estimated from the temperature dependence of the rate [42] (see above).

3.4.3 The Reduction of Dioxygen

The sequence of reactions in which dioxygen is reduced to two molecules of water by four electrons, entering cytochrome oxidase one at a time from cytochrome c , must necessarily involve a number of partially reduced oxygen intermediates. Information about such species has mainly been derived from flow-flash experiments with the fully or partially reduced oxidase (Section 3.3.3), but some of these oxygen species have also been generated artificially by the addition of H_2O_2 to the oxidized enzyme [46]. Early evidence for oxygen intermediates was obtained by Wikström [47] in experiments in which the electron flow in mitochondria was reversed by an electrochemical potential across the membrane. Detailed reviews on the oxygen chemistry in cytochrome oxidase are available [4a,b, 48], and an outline of the reactions involved is given in Figure 7.

When O_2 reacts with the fully reduced cytochrome oxidase (R in Figure 7), a ferrous-oxy intermediate at cytochrome a_3 forms in a second-order reaction with a rate constant of $10^8 \text{ M}^{-1} \text{ s}^{-1}$ [49]. The rate saturates, however, at high concentrations of O_2 [50], indicating initial binding to another site prior to heme binding, and there is evidence that this site is reduced Cu_B [49b, 51]. The ferrous-oxy species was first observed at low temperatures by Chance et al. [11a] and named compound A (see Figure 7). It has also been observed by resonance-Raman spectroscopy [12b–d].

Compound A is converted to the P intermediate concomitantly with the oxidation of cytochromes a and a_3 (Figure 7) at a rate of $3.5 \times 10^4 \text{ s}^{-1}$ [49a, 52]. Even if P is shown as a peroxide (hence its name), the actual structure of this species is still a matter of debate. It has been suggested to be ferryl ($\text{Fe}^{4+}=\text{O}^{2-}$) cytochrome a_3 [53], but the fact that P is formed also in the reaction of the two-electron reduced enzyme with O_2 [52c, 54] speaks against this. As alternatives Fe^{5+} [55], Cu_B^{3+} [46a] or even a protein radical [46c,d, 56] have been proposed. It has been reported [46a,d] that no correlation exists between the radical EPR signal and the concentration of any intermediate, including P, but it should be noted that a radical was first observed in

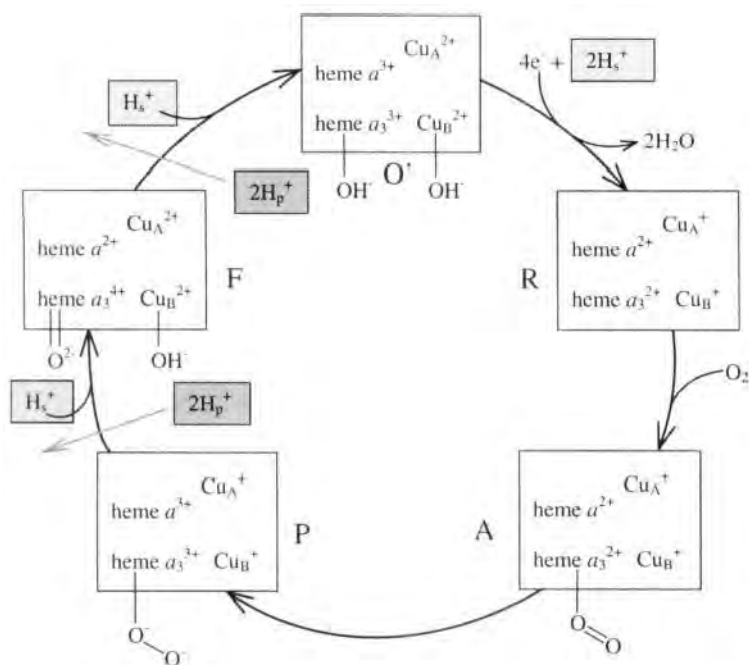

Figure 7. The catalytic cycle of cytochrome oxidase.

experiments, in which intermediates were trapped during turnover by rapid-freeze techniques [57]. In addition, a protein radical is also formed, when the mixed-valence oxidase reacts with O_2 [56]. Isotope-labeling experiments have clearly shown that the observed EPR signal is associated with a tyrosine radical [46d], most likely Tyr244 (bovine numbering), which is covalently linked to the Cu_B ligand His240 [58].

As just discussed, reactions with H_2O_2 can be used to generate P [46], but recently it has been shown that a species ($\text{Fe}^{4+}=\text{O}^{2-}$, Cu_B^+) is formed, when the mixed-valence enzyme reacts with H_2O_2 [59], and this species is not an intermediate in the reaction of the fully or partially reduced oxidase with O_2 . It may, however, become useful for investigations of the role of Cu_B in the proton-pump mechanism, since it has this ion reduced.

The conversion $\text{P} \rightarrow \text{F}$ (Figure 7) is accompanied by an electron equilibration between Cu_A and cytochrome a , and its rate is pH-dependent [60] and displays a kinetic isotope effect in D_2O [60b]. Consequently, it has been suggested [51, 60a,c] that the formation of F is controlled by the protonation of the binuclear site. The conclusion that F really is a ferryl ion intermediate is supported by resonance-Raman measurements [61].

In the final phase of the dioxygen reaction, cytochrome a donates an electron to F with the concomitant uptake of a proton [60] (Figure 7), and the fully oxidized enzyme is formed [52b, 60b,d]. This has at least one OH^- bound at the binuclear center [61, 62]. Like the previous step ($\text{P} \rightarrow \text{F}$), the rate of formation of O is sug-

gested to be limited by proton transfer [60b]. It has been reported [47b, 63] that the $P \rightarrow F$ and $F \rightarrow O$ transitions are the only steps in the entire catalytic cycle that are coupled to proton translocation, but this has been questioned [64]. In addition, recent work by the Wikström group [65] also gives a more complex picture. The energy for proton translocation is harnessed during the O_2 -reduction phase, but only half of it is utilized for proton pumping during the oxidation of the reduced enzyme; the other half is released, when the O_2 -oxidized enzyme is re-reduced.

3.4.4 Coupling between Electron and Proton Transfer

A revelation in the crystal structure of the *Paracoccus* cytochrome oxidase [6] was the identification of two possible proton pathways, now commonly called the K- and the D-pathways, leading from the proton uptake side of the membrane to the binuclear center, as illustrated in Figure 8; there were also indications, although less clear, of a proton-exit pathway (Figure 8). Putative proton pathways were also identified in the bovine oxidase [66], with some similarities to the proposed pathways in the bacterial oxidase. Originally, the D-pathway was assigned to translocated protons and the K-pathway to substrate protons (protons consumed in dioxygen reduction) [6], but later site-directed mutagenesis experiments of the residues shown

Figure 8. Schematic view of possible proton transfer pathways in subunit I.

in Figure 8 (K362, T359, D132 and E286) [67] forced a revision of this assignment. The present picture is one in which the two channels are used for different parts of the catalytic cycle (see [4b]). Thus, the K-pathway is used solely for proton uptake coupled to the initial reduction of cytochrome a_3 -Cu_B, whereas the D-pathway is used for the proton uptake in the $P \rightarrow F$ and $F \rightarrow O$ transitions. However, substrate protons also use the D-pathway during these steps.

The identity of the group in the vicinity of cytochrome a_3 , which releases a proton on oxidation of this heme (see Figure 4), as concluded from electron-backflow experiments with the mixed-valence oxidase [26, 41a] (see Section 3.4.2), is not known, but it has been suggested to be OH⁻ coordinated to the metal [26]. This could also be the group which, when protonated, was found to stabilize the reduced form of cytochrome a_3 in the normal, forward reaction [68]. The redox state of this center is, however, not always controlled in such a direct manner. For example, ET $a \rightarrow a_3$ in the $P \rightarrow F$ transition is prevented before a proton is taken up, because this is necessary for the Cu_A $\rightarrow a$ ET (60b, 69).

The uptake of protons via the D-pathway has been proposed to be facilitated by a hydrogen-bonded network of H₂O molecules, forming a proton wire [70]. However, even at high resolution, only one ordered H₂O molecule is seen [58, 71]. The proton-exit pathway has not been definitely identified, but recent experiments with mutations in arginine residues (R438 and R439; bovine enzyme numbering) with the related cytochrome bo_3 [72] suggest that it starts with the propionate side chain of the cytochrome a_3 heme group. This, in its anionic form, is proposed to accept a proton from E242 in a continuation of the D-pathway and then donate it to the arginine residues in the exit pathway.

3.5 Concluding Remarks

The reason for the great interest in the ET processes in cytochrome oxidase is ultimately to understand how these are coupled to proton pumping. Even if a good deal is known about the coupling between ET and proton transfer in the enzyme (Section 3.4.4), mechanisms for the proton pump remain largely hypothetical. In principle, two types of pump mechanisms can be envisaged: 1) Indirect-coupling mechanisms, in which the proton binding occurs at a site separate from the redox change and is mediated by redox-coupled conformational changes; and 2) direct-coupling mechanisms, in which the proton-binding group is directly associated with a redox center. Redox-linked conformational changes have been found in a crystal-structure study with the bovine enzyme [58], and subtle structural changes have also been observed in the bacterial oxidase by Fourier transform-infra-red (FT-IR) spectroscopy [73]. Most investigators favor direct-coupling mechanisms, however. One such mechanism, named the histidine cycle [74], involves dissociation and protonation of one of the histidine ligands to Cu_B. Recent crystallographic data show, however, that Cu_B does not change ligation on reduction [75]. Michel [64] has

proposed a radically different type of mechanism, largely based on considerations of electrostatic interactions [76], but continued exchanges in the literature [77] demonstrate that a consensus on pump mechanism has not been achieved. A challenging task for future research will be to move pump mechanisms from the realm of hypotheses to concrete reality.

Acknowledgments

I would like to thank Dr. Pia Ädelroth for useful discussions and for providing Figure 1, 3, 4 and 7; I am also indebted to Mr. Johan Leckner for preparing Figure 8. My own work has been supported by the Nobel Institute for Chemistry.

4 Redox Enzymes: Correlation of Three-Dimensional Structure and Mechanism for Heme-Containing Oxygenases and Peroxidases

Alycen E. Pond, Amy P. Ledbetter, Masanori Sono, David B. Goodin, and John H. Dawson

4.1 Introduction

Heme proteins are arguably the most versatile class of proteins in biology. This group of metalloproteins contains a common heme prosthetic group, yet performs a wide variety of chemical reactions including electron transfer (cytochromes) [1, 2], oxygen activation and insertion (cytochrome P450s) [3–6], oxygen transport (hemoglobin and myoglobin) [3, 7, 8], substrate oxidation (peroxidases and catalases) [9–11], and nitric oxide biosynthesis (nitric oxide synthase) [12, 13]. The heme prosthetic group consists of a highly symmetrical and conjugated protoporphyrin IX macrocycle coordinated to an iron atom [2]. As shown in Figure 1, this group, also termed heme *b*, has two propionate groups, two vinyl groups, and four methyl groups as substituents on the porphyrin ring system. A unique property of the heme prosthetic group is the significant electron and spin delocalization possible among the porphyrin macrocycle, the centrally ligated iron, and the two axial ligands [14–18]. The ability of the porphyrin macrocycle to efficiently redistribute the net atomic charges and unpaired spin density plays a key role in the formation and stabilization of the various heme species required for function [14–18]. Modifications in either the level of conjugation or the substituents on the ring structure influence the electronic properties of the system, and thus result in distinct reactivity and spectroscopic properties [19].

The utilization of heme *b* in the coupling of substrate oxidation to dioxygen or peroxide reduction is seen for three types of heme-containing proteins: oxygenases (Reaction 1A/1B), oxidases (Reaction 2), and peroxidases (Reaction 3). There are two classes of oxygenases where either one oxygen atom from molecular oxygen (or hydrogen peroxide, Reaction 1B) is incorporated into the substrate and the second atom is reduced to water (monooxygenases) or both oxygen atoms are incorporated to give a doubly oxygenated product (dioxygenases). Oxidases and peroxidases do not produce an oxygenated product, rather substrates are oxidized as molecular

Figure 1. Structure of protoheme IX (iron protoporphyrin IX, heme *b*).

oxygen or hydrogen peroxide are reduced to water, respectively. While all three classes of enzymes possess the same heme core, their catalytic function varies greatly. The basis for this variance stems from the three factors that control the properties of metals in biological systems: (i) the coordination state of the metal complex; (ii) the nature of the axial ligands in the fifth and sixth coordination sites; and (iii) the protein environment enclosing the metal complex including the polarity of the surroundings and the accessibility of substrates and solvent to the metal [3]. Monooxygenases have various structural features that are not shared by the peroxidases, and vice versa [3]. An understanding of how these differences correlate to enzyme function is essential in defining the relationships between oxygenases and oxidases. In this review we provide updated accounts of the mechanisms of heme-containing monooxygenases and peroxidases, with particular emphasis on the relation of their respective mechanisms to their high-resolution X-ray crystal structures.

4.2 Cytochrome P450

4.2.1 Introduction

The monooxygenase family has the catalytic ability to incorporate an oxygen atom from molecular oxygen to yield a singly oxygenated product while reducing the second oxygen to water. In the years before 1955, the sole role of oxygen in biological systems was believed to be as an electron acceptor in dioxygen-utilizing oxidases or dehydrogenases. In that year, Mason et al. [20] and Hayaishi et al. [21] independently demonstrated through $^{18}\text{O}_2$ labeling experiments that one or both oxygen atoms from molecular oxygen can be incorporated into organic molecules following enzymatic oxidation. The enzymes that incorporate oxygen atoms from dioxygen were termed “oxygenases” by Hayaishi [22]. Shortly after the discovery of oxygenases and their enzymatic activity, Garfinkel [23] and Klingenberg [24] independently described the presence of a carbon monoxide (CO)-binding pigment in liver microsomes, which exhibited unusual absorbance maxima near 450 nm in the ferrous-CO minus ferrous difference spectrum. Omura and Sato [25] later identified this pigment (“P”) as a heme protein containing a protoporphyrin IX (Figure 1) prosthetic group and assigned it the name “cytochrome P450”.

Enzymes of the P450 superfamily are by far the best characterized of all heme-containing monooxygenases, and are extensively distributed throughout the plant, animal, and microorganism kingdoms. To date, more than 500 isozymes have been cloned and sequenced with enzymatic activities covering a vast variety of reactivities including hydroxylation of inactivated alkanes, conversion of alkenes to epoxides, arenes to phenols, and sulfides to sulfoxides to sulfones (Figure 2). The hydroxylation of various harmful organic molecules by P450 enzymes greatly increases the solubility of the organic substrate, thereby facilitating their excretion from biological systems. In contrast to their beneficial roles, P450 enzymes can also transform certain otherwise nonreactive molecules such as benzo(a)pyrene into highly reactive carcinogens [3], making P450 enzymes attractive targets for cancer-related drug design and development.

With the exception of microbial P450 enzymes, the majority of P450 proteins are membrane-bound, being associated with either the inner mitochondrial or endoplasmic reticulum (microsomal) membrane. Initial efforts to release the membrane-bound P450s from the membrane by detergent solubilization led to a loss of monooxygenase reactivity, as well as a shift the characteristic 450 nm absorbance peak to 420 nm in the difference spectrum [25]. Subsequently, successful solubilization and purification of the active form of the P450 proteins and associated electron transport proteins were achieved for the mitochondrial and microsomal P450s by Estabrook and Coon and their respective coworkers [26, 27]. Gunsalas and coworkers [28] discovered a soluble camphor-inducible bacterial monooxygenase P450 (P450CAM) system in *Pseudomonas putida*. The solubility of P450CAM allows large quantities to be purified for detailed mechanistic and spectroscopic studies, as well as successful crystallographic analysis. The crystal structure determined by Poulos and coworkers [29–33] provides researchers with a model to study

the relationship between the P450s and their substrates, making P450CAM the preferred vehicle for studying the relationship between structure and function of the P450 family.

4.2.2 Reaction Cycle of P450

Electron transport systems

In catalyzing its monooxygenase reaction, P450 can utilize either NADH or NADPH as an electron source. The electron transport system varies among the P450 proteins, and thus allows for an organization of the superfamily into smaller classes. Most bacterial and mitochondrial P450 systems are termed Class I P450s, utilizing flavin and iron–sulfur prosthetic groups for electron transfer from NAD(P)H [34]. Figure 3A illustrates such a system where reducing equivalents flow from NAD(P)H to a FAD-containing protein to an iron–sulfur protein to the P450. Microsomal systems are termed Class II P450s and employ a single flavoprotein, NADPH-cytochrome P450 reductase, containing both FAD and FMN components to shuttle electrons from NADH to the P450 (Figure 3B) [34]. P450BM-3 is an unusual bacterial P450 from *Bacillus megaterium* that is a natural fusion protein consisting of a P450 domain and a NADPH-cytochrome P450 reductase domain that enables the protein to be self-sufficient (Figure 3C) [34, 35]. Finally, P450nor from *Fusarium oxysporum* is a Class IV P450 that appears to accept electrons directly from reduced pyridine nucleosides without intervening electron carriers (Figure 3D) [36].

The reaction cycle and intermediates

The common feature of P450 enzymes is their utilization of a cysteine-ligated heme active site to catalyze their respective monooxygenase chemistry. The monooxygenation reaction catalyzed by P450CAM in the hydroxylation of (1*R*)-camphor is shown in Reaction 4. The reaction cycle determined for P450CAM (Figure 4) is likely shared by most members of the P450 family [37], and involves four well-characterized and isolatable complexes, 1–4, [4, 37]. The substrate-free resting state, 1, is six-coordinate low-spin with a proximal cysteine residue from the protein and a distal water molecule from the solvent serving as the axial ligands (Figure 5B). Addition of camphor displaces the solvent molecule, yielding a five-coordinate high-spin complex, 2, with a vacant coordination site on the distal side of the heme that will ultimately be available for dioxygen binding. The shift of the iron spin

state from low- to high-spin upon substrate binding results in a significant increase in the redox potential (E°) of the heme iron (-330 to -173 mV versus NHE). As seen in Reaction 1A, the activation of molecular oxygen for monooxygenase chemistry requires the input of two electrons. For P450CAM, these electrons are provided by NADH via two electron transport proteins (Figure 3A): putidaredoxin reductase (a FAD-containing protein) and putidaredoxin (an iron-sulfur protein). Substrate binding facilitates electron donation from the reduced putidaredoxin

The site of hydroxylation on the camphor molecule is denoted with an arrow.

catalytic cycle [38, 39], is proposed to give a ferric peroxide complex, **6a**, which can then be protonated to yield a ferric hydroperoxide species, **6b**. Addition of a second proton to this outer oxygen leads to heterolytic cleavage of the O–O bond, releasing water and generating the proposed oxo-ferryl ($\text{O}=\text{Fe}^{\text{IV}}$) porphyrin radical intermediate, **7**. Intermediate **7** is equivalent to the high-valent iron-oxo species of the peroxidases called Compound I. Compound I is the most likely candidate for the “reactive oxygen” form of P450 that hydroxylates inactivated hydrocarbon substrates. Abstraction of a hydrogen atom from the substrate by **7** forms a substrate-based carbon radical and an iron-bound hydroxyl radical. Radical rebound then yields the hydroxylated product and regenerates **1** [3, 4, 6, 40].

The short circuit or peroxide shunt

The cycle can also be turned over by two shunt pathways (pathway **A** and **B** in Figure 4). First, oxygen atom donors ($[\text{O}]$) such as iodosobenzene and peracids can replace the two electrons and dioxygen required for the normal catalytic cycle and react directly with **2** to generate oxygenated products likely through intermediate **7** (Pathway **A**) [4, 27, 41]. Similarly, some P450 proteins are able to replace molecular oxygen and NADH with hydrogen peroxide in a manner similar to the peroxidases. Pathway **B** illustrates the utilization of hydrogen peroxide to form **7** from substrate-bound ferric P450CAM (**2**) via the ferric hydroperoxide species, **6b** (4). Conversely,

pathways **C** and **D** illustrate the uncoupling of NADH oxidation and oxygen transfer. Protonation of the iron bound oxygen in **6b** releases hydrogen peroxide generating the five-coordinate ferric state, **2**, with no oxygen transfer to substrate (pathway **C**), a two-electron uncoupling reaction. Also, two-electron reduction and diprotonation of the oxo group in **7** gives a second molecule of water, regenerates complex **2**, and no oxygenated product yielding a four-electron uncoupling reaction (pathway **D**) [42–44].

Poulos has discussed the most likely causes of these latter two uncoupling reactions based on examination of the crystal structures of complexes of P450CAM with various camphor analogues and of site-directed mutants of P450CAM with modified substrate-binding sites [45]. The presence of excess solvent molecules near the heme, as well as an increase in substrate mobility, have been suggested as possible explanations for the uncoupling of electron transfer to oxygen transfer. Despite being the ultimate source of the protons needed for catalytic turnover, the presence of excess solvent within the active site could promote various uncoupling reactions. In related work, Sligar and coworkers have demonstrated that steric factors on the distal side of the heme strongly influence the coupling of oxygen and electron transfer in P450CAM and the partitioning between two- and four-electron uncoupling [42].

4.2.3 Molecular Structure of P450

In 1985, P450CAM was the first P450 protein to be successfully crystallized and have its structure determined [29]. The protein has an asymmetrical triangular shape consisting of 12 α helices and five anti-parallel β sheets (Figure 5A). The heme prosthetic group is deeply embedded into the hydrophobic interior of the protein, sandwiched between two long α helices, with no significant exposure to the surface of the protein. Previous spectroscopic investigations of P450CAM established that a cysteine residue serves as the endogenous ligand donated by the protein [4]. This finding was substantiated by the crystal structure identifying Cys357 as the proximal ligand to the heme (Figure 5B). Several years later, the structure of the P450 domain of P450BM-3 was determined [46], giving researchers models for a class I (P450CAM) and a class II (P450BM-3) P450. A side-by-side comparison of these two proteins can be seen in Figure 6. Subsequently, the successful crystallization and crystallographic analysis of two other class I P450s, P450TERP [47] and P450eryF [48, 49], a class IV P450, P450nor [50, 51], and P450csa [52] have been achieved. Additional structures of P450CAM and P450BM-3 in various coordination states and oxidation states [53–55] and several mutant forms of P450CAM [56–58] are also available.

Comparison of the amino acid sequences of members of the P450 family has revealed two areas of sequence similarity [59]. One region contains the proximal cysteine ligand along with the residues comprising its binding pocket. The second area of conservation corresponds to Thr252 of P450CAM located on helix I, which interacts directly with the bound dioxygen molecule of the P450–O₂ complex (Figure 5B). Both these areas are vital for efficient catalytic turnover, and will be discussed in later sections. With the availability of the structural data of the above

Figure 6. A side-by-side comparison of the secondary structures of P450CAM (left) and P450BM-3 (right) generated from their respective X-ray coordinates [58, 210]. Helical regions, β -sheet regions, and the heme group are shown.

P450s, it appears that the overall structural protein fold and the spatial organization of the heme-binding site are highly conserved, despite a less than 20% sequence identity among the proteins. Closer examination of these structures shows that there is ample diversity in the primary, secondary, and tertiary structures of the proteins to accommodate their wide variety of substrates, redox partners, and cellular locations. Detailed structural comparisons of these P450 proteins by Poulos et al. [33] and Peterson and colleagues [34, 59] can be found in the P450 literature.

In this new millennium, significant advancements have already been made in the crystallographic study of P450 proteins. First, McRee and coworkers produced the first X-ray crystal structure of a microsomal P450, P450 2C5 [60]. Comparison of this structure with those of microbial P450s indicates that the overall fold of the two types of P450 proteins is similar, as is the structural core surrounding the heme-binding site. However, significant structural differences exist between the substrate binding sites, and the modes of interaction with both electron donors and the membrane. Close analysis of the P450 2C5 structure provides a basis for the study of the interaction of a microsomal P450 with the endoplasmic reticulum, its substrate, and its redox partner. McRee and coworkers suggest a monofacial attachment of P450 2C5 to the membrane via a broad, hydrophobic surface that is adjacent to the anchor provided by a transmembrane helix at the N terminus [60]. The orientation of P450 2C5 relative to the membrane positions the electrostatic dipole of the P450 in such a manner to maximize the attraction between the protein and its reductase [60]. The entrance to the substrate access channel is located in the membrane attachment surface, suggesting that lipophilic substrates and products can enter or exit the P450 directly from the bilayer. An alternative substrate access

channel is also present, which would allow more water-soluble metabolites to exit directly into the cytoplasm [60]. As there is high sequence similarity between P450 2C5 and 91 other members of family 2 P450 enzymes [60], this structure and its analysis will provide researchers with a template by which to model the interactions of other microsomal P450s.

In a second crystallographic stride forward, Schlichting et al. have obtained structures for previously nonisolatable intermediates in the hydroxylation reaction of camphor by P450CAM utilizing trapping techniques and cryocrystallography [61]. The structure of the oxyferrous complex (**6a**) has been determined to a 0.91 Å resolution, showing a dioxygen molecule which binds end-on to the heme iron with the outer oxygen atom pointing towards Thr252. The bond distance between the heme iron and the inner oxygen is 1.8 Å with a Fe–O–O tilt angle of 132° [61], in agreement with previous extended X-ray absorption fine structure (EXAFS) [62] and resonance Raman [63] studies. In addition to altering the electron density surrounding the heme group, the binding of dioxygen also affects the distal binding pocket in two crucial ways. First, a new ordered solvent molecule (WAT 901) is now present near both the outer oxygen atom and the hydroxyl group of Thr252. Secondly, the backbone atoms of the highly conserved Asp251 and Thr252 have undergone a conformational change in which the carbonyl of Asp251 has flipped 90° towards Asn255, and the amide nitrogen of Thr252 has rotated towards the heme pocket [61]. These alternations result in new hydrogen-bonding interactions among the distal protein residues that appear to stabilize the new solvent molecule, WAT 901.

The addition of a second electron through irradiation of crystals of the oxyferrous complex with long-wavelength X-rays alters the electron density at and around the P450 active site [61]. Difference maps suggest that cleavage of the dioxygen bond has occurred, leaving a single oxygen atom bound to the heme iron. The electron density above the heme is too small to accommodate two oxygen atoms, and is best fit with a single oxygen atom bound to the heme at a distance of 1.65 Å [61]. This distance is much shorter than the 1.8 Å distance of an iron–oxygen single bond, and is in close agreement with computational (1.66 Å) [64] and EXAFS measurements for an oxo ferryl complex in a peroxidase [65]. This potential glimpse of compound I gives credence to the proposed catalytic mechanism of P450CAM and may translate to other P450 systems.

4.2.4 Mechanism of Oxygen Activation

A distinguishing characteristic of monooxygenases and peroxidases from the globins is the ability of the former two proteins to heterolytically cleave the O–O bond (Reaction 5A), while the latter utilize homolytic cleavage (Reaction 5B). This subtle difference in mechanism allows monooxygenases and peroxidases to perform their wide variety of catalytic activities, while globins serve as oxygen carriers. As can be seen in Reactions 5A and 5B, the high-valent Compound I species is formed only when both electrons in the O–O bond go with the leaving group, i.e., heterolytic cleavage. When the bond is cleaved homolytically, as seen for the globins, the

electrons in the bond are split between the two oxygen atoms, forming Compound II, a less reactive oxo intermediate. The ability of monooxygenases and peroxidases to cleave the O–O bond heterolytically is a direct result of their respective active site protein environments, particularly the proximal ligand and catalytically active protein residues on the distal side of the heme.

The “push–pull” mechanism of the peroxidases

Heme-containing peroxidases carry out heterolytic O–O bond cleavage starting from the ferric state and binding hydrogen peroxide to form the high-valent iron-oxo intermediate, Compound I. The crystal structure of cytochrome *c* peroxidase, a prototypical heme-containing peroxidase, led Poulos to propose a “push–pull” mechanism for the formation of Compound I [66]. In this system, it is proposed that heterolytic cleavage is achieved by a combination of electron density “push” from the anionic proximal histidine, and “pull” by the distal histidine and arginine couple (Figure 7) [66, 67]. The “push” is provided by the proximal histidine ligand whose electron donor capabilities are enhanced due to a strong hydrogen-bonding interaction (partial deprotonation) with a neighboring carboxylate group, thereby increasing its imidazolate character relative to the corresponding histidine ligand of hemoglobin or myoglobin. This anionic character may also serve to stabilize the higher oxidation states of the heme iron during catalysis. Simultaneously, the distal histidine accepts a proton from the inner oxygen of the bound hydrogen peroxide and transfers it to the outer oxygen to generate a good leaving group. The distal histidine works in concert with a strategically positioned cationic arginine residue that serves to stabilize the developing anionic charge on the outer oxygen during bond cleavage. The combination of the distal histidine and arginine provide the “pull” effect. Recent site-directed mutation of residues on both the proximal and distal side supports the push–pull effects on the formation of Compound I of CCP

Figure 7. Schematic view of the “push-pull” mechanism for O–O bond cleavage of an iron-bound peroxide in thiolate-ligated (left) and histidine-ligated (right) systems such as P450 and HRP, respectively. (Adapted from Ref. [6].)

[66–71], especially the replacement of the distal histidine with a leucine residue which suppressed the rate of Compound I formation 10⁵-fold [67, 69, 70].

The “push” effect of the proximal cysteine ligand for P450

Nearly 25 years ago, Dawson proposed that the P450 proximal thiolate ligand serves as a strong internal electron donor to facilitate O–O bond cleavage to generate Compound I (Figure 7) [72]. Three lines of evidence for the “push” of the cysteinate ligand have been reported. First, bound distal thiolates show enhanced basicity *trans* to the endogenous cysteinate of P450CAM relative to parallel myoglobin adducts [73]. Second, significant differences have been reported for the affinities of anionic ligands to ferric P450 and myoglobin, with anionic ligands having much lower affinity for ferric P450CAM than ferric myoglobin, presumably due to the anionic character of the proximal thiolate ligand [74]. Finally, Dawson and coworkers have observed shifts in the in the X-ray absorption energies for thiolate-ligated heme iron derivatives relative to those lacking a thiolate ligand to provide a direct measure of the strong electron-releasing nature of the thiolate axial ligand [75]. More recently, studies using a His → Cys myoglobin mutant [76] or a thiolate-ligated porphyrin model system [77] demonstrate that the thiolate-ligated systems favor the heterolytic cleavage of the O–O bond compared to wild-type myoglobin

and neutral histidine-ligated porphyrin models that predominantly cleave the O–O bond homolytically. Once the O–O bond is cleaved heterolytically, the anionic character of the thiolate ligand helps to stabilize the high-valent nature of Compound I.

In 1999, Hager and coworkers provided the first evidence that the strong anionic character of the thiolate ligand may not be the only determining factor in the differentiation between homo- and heterolytic cleavage of the O–O bond. Replacement of the proximal thiolate ligand in the related peroxidase enzyme of chloroperoxidase (CPO), a versatile heme enzyme from *Caldariomyces fumageo*, with a histidine resulted in a recombinant mutant that retains most of its chlorination, peroxidation, epoxidation, and catalase activities [78]. This retention of activity despite the loss of thiolate ligation indicates that the environment of the distal pocket may play as important a role as the proximal ligand in differentiating between homo- and heterolytic cleavage of the O–O bond. CPO has a very polar distal environment that is typical of peroxidases. As evidenced by the high activity levels of the Cys → His mutants, this polar environment likely plays a major role in maintaining the diverse catalytic activities of this enzyme.

The proton shuttle in P450

The “push” of the thiolate ligand cannot, by itself, accomplish heterolytic cleavage of the O–O bond (Figure 7). In addition, there must be a source of protons to enable the outer oxygen atom of the bound peroxide (Figure 4, species **6a**) to leave as water. Theoretical studies by Loew and Harris [64] indicate that the protonation of the outer oxygen leads to significant weakening of the O–O bond. This weakening is manifested in both an increase in O–O bond length from 1.33 to 1.46 Å, and a decrease in the bond order from 0.87 to 0.48 [64]. However, only the addition of the second proton results in the cleavage of the dioxygen bond, resulting in the formation of Compound I [64]. These results provide strong support for consecutive or simultaneous double protonation of the outer oxygen atom of the ferrous dioxygen complex being the ultimate cause of O–O bond breakage.

Extensive study of the P450CAM active site has identified two potential routes for proton transfer (Figure 8). The first involves two highly conserved residues, Thr252 and Asp251 [58, 79–83]. The second possibility is via a water chain and the highly conserved Glu366 [84]. Sligar and coworkers have proposed that Thr252 and Asp251 form a proton relay network that works in conjunction with two other charged amino acids to reach the surface solvent and provide a conduit for protons [58, 80–83]. Replacement of Thr252 with alanine (T252A) results in a drastic drop in hydroxylation activity (~95 %) without a simultaneous decrease in NADPH and O₂ consumption (i.e., increased uncoupling) [82, 85]. Similarly, replacement of the corresponding Thr268 with alanine (T268A) in P450BM-3 results in a decrease in substrate (laurate) hydroxylation (~85 %) and an increase in uncoupling [86]. However, in P450CAM substituting Thr252 with either a serine or an O-Me-Thr residue produces an enzyme that retains high activity [79, 87]. The mechanistic results obtained with these mutants indicate that the role of Thr252 in the hydroxylation mechanism is to provide a hydrogen bond rather than a proton during

Figure 8. A schematic view of the proposed proton shuttle in the distal pocket of P450CAM. Distal residues and the heme were generated using the X-ray coordinates [58]. Dashed lines represent hydrogen-bonding interactions as determined in Ref. [61]. Water molecules are represented by isolated spheres, with WAT 901 and WAT 902 in positions determined in Ref. [61].

turnover (Figure 8). The recent crystal structure of the oxyferrous complex of P450CAM confirms this assignment, showing Thr252 within hydrogen bonding distance to the bound dioxygen molecule as well as a potentially catalytic solvent molecule, WAT 901 [61].

Replacement of Asp251 with asparagine (D251N) decreases the rate of hydroxylation by two orders of magnitude, with relatively little uncoupling and shifts the rate limiting in the catalytic cycle [58, 80, 88]. Based on isotopic and crystallographic studies of wild-type and D251N P450CAM, *Sligar and coworkers proposed* a proton shuttle involving two new solvent molecules in the active site, with Asp251 serving as a “carboxylate switch” between solvent-accessible residues and the cata-

lytic water molecules (Figure 8) [79]. However, the availability of recent structural data has altered this proposal somewhat, with Asp251 now serving as a “carbonyl switch” that stabilizes WAT 901 instead [61].

The intrinsic diversity of the family must be kept in mind when trying to apply results for P450CAM to the P450 superfamily. In P450eryF, a P450 that catalyzes the hydroxylation of 6-deoxyerythronolide, there is an alanine (Ala245) in the position corresponding to Thr252 in P450CAM. Mutation of this residue in P450eryF to a threonine (A245T) results in a dysfunctional protein, similar to the opposite mutation in P450CAM (T252A). Therefore, P450eryF must utilize a varied source of protons in its catalytic cycle. Molecular dynamic simulations by Harris and Loew [64, 84] have identified a stable hydrogen-bonding network leading from the outer oxygen of the iron-bound dioxygen to the carboxylic oxygen of Glu360, a highly conserved residue in the P450 family. This residue is located in a solvent-accessible channel, and is likely the ultimate source of protons in P450eryF [64, 84]. The corresponding residue in P450CAM, Glu366, does not appear to serve the same purpose in the catalytic cycle as its mutation to a methionine shows little effect on catalytic activity [89]. Instead, structural data suggest that this residue may “anchor” a solvent chain that extends between Thr252 and Glu366 (Figure 8) [61]. Therefore, neither the role of a specific amino acid nor the consequence of a mutation can be inferred for one P450 enzyme based on the results for another isozyme.

4.3 Nitric Oxide Synthase

4.3.1 Introduction

Nitric oxide ($\bullet\text{NO}$) is a diatomic, reactive radical that has become the focus of intense scientific investigation during the past two decades. Its role as a biological messenger places this small molecule at the heart of a number of complex regulatory mechanisms in diverse biological systems. The ability of $\bullet\text{NO}$ to diffuse freely from its point of origin rather than using classical biological trafficking routes (i.e., specific transporters or channels) makes regulation dependent on its actual biosynthesis, and not its movement through the body. Before 1981, $\bullet\text{NO}$ biosynthesis was believed to be restricted to bacteria that engaged in nitrification and denitrification reactions [90]. For the first time in 1981, nitrogen oxides were conclusively demonstrated as significant products in mammalian metabolism [90]. Building on this discovery, numerous research groups have focused on the role of $\bullet\text{NO}$ in mammalian systems. Stemming from this research, $\bullet\text{NO}$ has been implicated as a neurotransmitter in the brain, a vasodilator in smooth muscles, and an immunocytotoxic reagent in macrophages [90]. As the potential functions of $\bullet\text{NO}$ become more established, scientific attention has shifted towards its regulation and therefore to the enzyme responsible for its biosynthesis, nitric oxide synthase (NOS). Following initial sequencing and development of a recombinant system in 1991, the amount of knowledge accumulated about NOS is astounding.

Neuronal NOS 160 kDa**Endothelial NOS 133 kDa****Inducible NOS 130 kDa****Oxygenase Domain****Reductase Domain**

Figure 9. Map of the primary amino acid sequence of nNOS, eNOS, and iNOS. A calcium-calmodulin binding region separates the oxygenase and reductase domains. The reductase domain contains binding sites for two flavin cofactors (FAD and FMN) as well as a binding site for the electron donor, NADPH. The oxygenase domain contains binding sites for the heme, the substrate (L-arginine), and tetrahydrobiopterin (H₄B). (Adapted from Ref. [90].)

4.3.2 The Isoforms

To date, three isoforms of NOS have been identified: neuronal NOS (nNOS, NOS-I, brain), inducible NOS (iNOS, NOS-II, immune system), and endothelial NOS (eNOS, NOS-III, cardiovascular system). These isoforms have been purified from different sources, and many have been cloned and functionally expressed [91]. Each isoform of NOS is comprised of a N-terminal oxygenase domain and a C-terminal reductase domain connected by a 30-amino acid recognition sequence for the binding of the calcium/calmodulin (Ca²⁺/CaM) complex (Figure 9) [12, 90, 92–95]. The oxygenase domain contains binding sites for the heme, the cofactor tetrahydrobiopterin (H₄B), and the substrate, L-arginine (L-Arg). The reductase domain contains binding sites for NADPH, flavin mononucleotide (FMN), and flavin-adenine dinucleotide (FAD) that shuttle electrons to the heme center to couple product formation. The Ca²⁺/CaM complex acts as a hinge between the oxygenase and reductase domains, allowing communication between domains [96, 97]. In nNOS and eNOS, the electron flavin-to-heme transfer must be initiated by the binding of the Ca²⁺/CaM complex, whereas iNOS is active at all times because Ca²⁺/CaM is always bound. Recently, work with iNOS indicates that the electrons flow between the oxygenase and reductase domains on adjacent subunits (Figure 10) [98]. This “domain swapping” provides a means for NOS to prevent uncoupling of NADPH oxidation and may provide a way for H₄B function or Ca²⁺/CaM control of heme iron reduction [98].

Dimerization of the oxygenase domains is essential for catalytic activity and for binding of the pterin cofactor [99]. Recent structural data for the dimeric oxygenase domains of NOS [100–102] reveal an extensive dimer interface that creates binding sites for the two pterins, sequesters the heme from the solvent, and helps to structure the substrate binding site (Figure 11). Upon dimerization, all three isoforms pro-

duce $\bullet\text{NO}$ by catalyzing the oxidation of L-arginine to L-citrulline and $\bullet\text{NO}$, via the intermediate, N^ω -hydroxy-L-arginine (NHA) (Reaction 6) [12, 92, 95]. The reaction is a variation on the hydroxylation reaction catalyzed by P450 enzymes; thus, it is not surprising that NOS and P450 are very similar biological machines. Both have a thiolate-ligated heme prosthetic group at their respective active sites, and utilize a FMN/FAD reductase system for electron transport from NADPH. With an exception of P450 BM-3, NOS is distinct from P450s in that NOS is a “self-sufficient” monooxygenase in which both the oxygenase and reductase domains are part of a single peptide. Unlike P450 BM-3 that is also self-sufficient by having a fused oxygenase and reductase domains in a single peptide [103], NOS employs a H_4B group, the function of which is poorly understood. However, it is required for efficient catalysis, and essential for $\bullet\text{NO}$ production [104].

Neuronal production of $\bullet\text{NO}$ is triggered when an activated neuron releases a chemical messenger (glutamate) from the presynaptic neuron to bind to receptor sites (N -methyl-D-aspartate) on the postsynaptic neuron. The transmission of this nerve impulse opens a channel in the receptor allowing the influx of calcium ions. These ions can then bind to calmodulin already present in the cell, forming a $\text{Ca}^{2+}/\text{CaM}$ complex that binds to and activates nNOS [90]. The $\bullet\text{NO}$ radical that is produced in turn activates soluble guanylate cyclase in the postsynaptic neuron and potentially in the presynaptic neuron.

Similar to the activation mechanism found in the neuronal cells, chemical messengers (e.g., hormones or acetylcholine) bind to their corresponding receptors on endothelial cell membrane. This binding triggers the opening on a membrane channel, resulting in a flow of calcium into the cell. Once in the cell, the calcium binds to a calmodulin molecule, forming the $\text{Ca}^{2+}/\text{CaM}$ complex that in turn activates eNOS through binding. As eNOS is bound to the inner surface of plasma membrane of the cell, the $\bullet\text{NO}$ produced diffuses freely into both the blood vessel and into the underlying vascular smooth muscles cells. In the blood vessel, $\bullet\text{NO}$ enters blood platelets and decreases their aggregation with each other and their adhesion to endothelial cells [90]. Within the muscle cells, $\bullet\text{NO}$ activates sGC, producing an increase in cyclic guanine monophosphate (cGMP) levels. cGMP decreases the amount of free calcium levels in the muscle cell, allowing the blood vessels to vasodilate [90].

Unlike nNOS and eNOS, inducible NOS does not require calcium for activation. Instead, the enzyme is synthesized in macrophages in response to cytokines. Once

synthesized, iNOS immediately begins production of $\bullet\text{NO}$ that diffuses at least partially into the nearby tumor cell. Once inside the cell, $\bullet\text{NO}$ can disrupt a number of cellular processes, including electron transport needed for adenosine triphosphate synthesis, and the tricarboxylic acid cycle. In addition, $\bullet\text{NO}$ can also inhibit the ribonucleotide reductase necessary for DNA synthesis and cell division [90].

4.3.3 The Molecular Structure of NOS

The recent advances in NOS structure analysis have shed light on the roles of the pterin, the substrate, and the newly discovered zinc ion in dimer formation and stabilization as well as catalytic activity. Work by numerous groups on iNOS (murine and human) [100, 101, 105–107], and eNOS (human and bovine) [101, 102] provides an intimate view of the various interactions between cofactors and protein–protein interplay in dimer formation. Structural work on the neuronal isoform of NOS is presently ongoing, with preliminary results indicating high structural similarity to published structures of the other NOS isoforms (T.L. Poulos, personal communication).

Prior to the elucidation of these structures, it was known that NOS must dimerize through the oxygenase domain for catalytic function [99]. Structures of the oxygenase dimer of both iNOS and eNOS reveal that dimer formation reinforces the substrate binding channel and sequesters two pterin molecules within two symmetry-related lariats (see Figure 11) [100–102]. The dimer interface is extensive with between 1200 and 2800 Å² of buried surface [100–102]. Additionally, conformational changes upon dimerization of iNOS expose the heme edge opposite of the center channel, and provide a possible interaction surface for the complementarily shaped reductase domain [100].

Similar to the P450s, the substrate (L-Arg) is held in place by hydrogen-bonding interactions that position the atom to be hydroxylated within 4 to 5 Å from the heme iron (Figure 12) [100–102]. Interactions of the L-Arg guanidinium group at the bottom of the heme pocket suggest a mechanism for $\bullet\text{NO}$ synthesis where the proton donation from the substrate to the iron-bound dioxygen facilitates heterolytic cleavage of the O–O bond, yielding Compound I [100]. This interaction serves to neutralize the guanidinium group, and discriminates between Compound I and the ferric superoxy species in the two steps of $\bullet\text{NO}$ synthesis. The only major difference between the binding modes of L-Arg and NHA in the active site results from the addition of the NHA hydroxyl group. The structure of this complex shows the oxime nitrogen (N^{ω}) of NHA projecting towards the center of the porphyrin macrocycle ~ 4 Å away from the iron [106]. This positioning leaves no proton readily available for the breakdown of the ferric superoxy complex to Compound I, thereby allowing the dioxygen species to serve as the active oxygen intermediate in the reaction of NOS with NHA. However, direct interaction between the ferric superoxy complex and NHA is unlikely. Modeling studies with the structure of NHA-bound iNOS indicate that the terminal oxygen of the ferric superoxy species is distant from the NHA hydroxyl group and therefore does not appear able to interact with this substrate moiety [106]. Instead, free radical addition of the ferric superoxy to the

Figure 12. Key catalytic residues and the location of L-arginine in the heme active site [100]. The heme is ligated to a cysteine residue with the sixth position vacant. Dashed lines represent hydrogen-bonding interactions between the substrate and the distal heme environment as depicted in Ref. [100].

NHA oxime or proton donation from protonated N^{ω} to the heme species are suggested as likely mechanistic pathways [106]. Regardless of the final mechanism, the L-Arg and NHA-bound structures of NOS imply that NOS catalysis selects between two different reductive activations of dioxygen.

The essential pterin cofactors of the NOS bind at the dimer interface ~ 13 Å apart and $\sim 40^\circ$ from coplanarity (Figure 11) [100–102, 106, 107]. The H_4B heteroatoms participate in a number of hydrogen-bonding interactions—most importantly with a tryptophan residue from the same subunit, and a phenylalanine residue from the adjacent subunit (Figure 13). These two residues maintain π -stacking interactions with the H_4B pteridine ring increasing both pterin affinity and $\bullet NO$ synthesis activity [100–102, 106, 107]. Additionally, the pterin interacts with the same heme propionate group as L-Arg and NHA (Figure 13), allowing allosteric interaction between the pterin and the substrate via the propionate group. Recent structural

data of NOS with H₄B bound, as well as other substituted and oxidized pterins, indicates that H₄B likely binds in its neutral form and fulfills roles ranging from dimer stabilization to acting as a redox cofactor or modifier of heme reactivity [106].

The most recent discovery revealed by structural NOS data is the positioning of a tetrahedrally coordinated zinc ion at the base of the dimer interface (see Figure 11). Seen first for eNOS [102], this divalent metal site has since been observed in iNOS [100, 101, 106] and nNOS (T.L. Poulos, personal communication). The zinc ion is coordinated to pairs of symmetry-related cysteine residues, and is equidistant from both pterin cofactors (~ 12 Å) and heme groups (~ 20 Å). This remote location from the catalytic heme iron, as well as its complete coordination by four cysteines (Figure 14A), is consistent with a structural rather than enzymatic role for the zinc ion. Structures of zinc-free iNOS show the formation of a self-symmetric disulfide bond (Figure 14B) across the dimer interface that adversely effects subunit association, formation of the pterin-binding site, and catalytic activity [107, 108], supporting the structural role proposed for the zinc site. In addition, the surface of the area closest to the zinc site in eNOS is the most electropositive region of the molecular surface, and provides an excellent docking site for the strongly electronegative reductase domain [102]. Similar calculations for iNOS reveal no such surface near the zinc site, and point instead to the surface surrounding the exposed heme edge as the potential site for reductase binding [108].

4.3.4 The Mechanism of NOS

Proposals regarding the NOS catalytic mechanism of the conversion of L-Arg to L-citrulline and •NO have ranged from sole participation of the heme cofactor (a P450-type mechanism) to interactions between the substrate, heme, and the H₄B cofactor. The conversion of L-Arg to NHA is a two-electron oxidation of one of the guanidino nitrogens of L-Arg. This step is believed to parallel a P450 hydroxylation reaction with direct involvement of the heme in oxygen activation [4, 6, 109]. In the second half of the overall reaction, the conversion of NHA to L-citrulline and •NO is a three-electron oxidation of the substrate involving electron removal, oxygen insertion, and carbon–nitrogen bond scission to form product [12, 90, 110]. NADPH stoichiometry for all three isoforms under multiple turnover conditions suggests that 1.5 mol of NADPH is consumed to generate 1 mol of •NO and L-citrulline [111–113]. Of these three electrons, the conversion of L-Arg to NHA utilizes two electrons, while the formation of •NO and L-citrulline from NHA requires the remaining 0.5 mol of NADPH. Related ¹⁸O₂ experiments demonstrated that the oxygen atoms incorporated into •NO and L-citrulline originate from different molecules of molecular oxygen [114, 115]. The interesting aspect of NOS chemistry is that the enzyme converts substrates (L-Arg, O₂ and NADPH) with an even number of electrons into products that also contain an even number of electrons (L-citrulline, water, and NADP⁺) plus the free-radical species, •NO [90].

Conversion of L-Arg to *N*^ω-hydroxy-L-arginine

The first half of the working mechanism shown in Figure 15 originates from proposals in the NOS literature [116, 117] involving the formation of a high-valent oxo

Figure 15. Proposed mechanism for the biosynthesis of nitric oxide from L-arginine. See text for details. (Adapted from Ref. [90].)

heme complex analogous to Compound I in P450 and peroxidase chemistry. Initially, the ferric five-coordinate largely high-spin resting state binds L-Arg to form the totally high-spin substrate bound complex (1). Upon addition of an electron from NADPH, the ferric-iron is reduced to the deoxyferrous complex (2). One equivalent of dioxygen binds to the ferrous heme iron to form the oxyferrous complex, shown in Figure 15 as the ferric superoxide resonance form (3). Addition of a second electron to 3 from NADPH is proposed to give a ferric peroxide complex (4) that can then be doubly protonated to lose water and yield the oxo-ferryl ($\text{O}=\text{Fe}^{\text{IV}}$) porphyrin radical intermediate (5). Unlike P450s where protons are shuttled in from the surface of the protein via a distal charge relay, structural data implicate the proton-rich guanidinium group of L-Arg as the proton source (Figure 16) [100]. The position of the terminal nitrogen 3.8 Å from the heme iron permits the donation of protons to the peroxo-iron, facilitating O–O bond cleavage and reduction of the guanidinium charge [100]. Following O–O bond cleavage, the substrate can then react with the remaining electrophilic oxo-iron species to form the hydroxylated product, NHA.

Similarities between NOS and P450 (e.g., thiolate-ligation to the heme, close proximity of the substrate to the active oxygen intermediate, and O_2 and NADPH requirements) provide a powerful argument for a P450-type reaction mechanism. However, other mechanistic proposals have been offered which liken NOS to an amino acid hydroxylase rather than to a P450. The reasoning behind an alternative catalytic pathway for NOS is two-pronged. First, hydrogen peroxide is unable to catalyze the formation of NHA from L-Arg. This reaction—also known as the peroxide shunt—allows hydrogen peroxide to replace O_2 and the two electrons from NADPH, and is well established for P450 enzymes. Second, experiments by Perry and Marletta determined that addition of exogenous nonheme iron increased nNOS activity [118]. This stimulation led to the proposal that the pterin and the nonheme iron are in close proximity such that both participate in oxygen activation and hydroxylation [118]. This catalytic mechanism would account for the inability of hydrogen peroxide to substitute for oxygen and NADPH. Recent crystallographic analysis of tyrosine hydroxylase [119] and NOS [100–102, 106] refute these proposed roles for mononuclear iron and the pterin by revealing little similarity between the two enzymes. In fact, no mononuclear metal binding site could be found in NOS [100–102, 106]. In light of this evidence, the monooxygenation of L-Arg by NOS likely follows a P450-type mechanism, despite the ineffectiveness of hydrogen peroxide in catalytic turnover.

Conversion of N^ω -hydroxy-L-arginine to L-citrulline and •NO

Single turnover experiments by Stuehr and coworkers have determined that only one exogenous electron is necessary for conversion of NHA to products [120]. These results argue against participation of the P450-like oxo-ferryl intermediate and instead favor a ferric-superoxide complex as the reactive oxygen intermediate in the catalytic mechanism. In the first half of the NOS reaction, the ferric superoxy complex is thought to be only an intermediate that leads to a “reactive oxygen species” capable of hydroxylating L-Arg, whereas in the second half it may react

Figure 16. Proposed L-arginine-assisted NOS oxygen activation. First, substrate L-arginine (only guanidinium shown) donates a proton to the peroxo-iron, facilitating O-O bond cleavage and conversion to a proposed oxo-ferryl π -cation radical species. The radical species then rapidly hydroxylates the neutral guanidinium to N^{ω} -hydroxy-L-arginine. (Adapted from Ref. [100].)

directly with the substrate, NHA. Following the formation of NHA (Figure 15), reduction of the regenerated ferric five-coordinate species (6) by an electron from NADPH yields a five-coordinate ferrous adduct (7). Dioxygen binds in the sixth coordination site to form the ferric-superoxide complex (8). A hydrogen atom from the NHA reduces the ferric-superoxide adduct to form the ferric-hydroperoxide complex (9) and a cation radical on the guanidino carbon of the substrate. The ferric-hydroperoxide species nucleophilically attacks the guanidino carbon ($^-\text{O}-\text{N}^+=\text{C}(\text{NH}_2)-\text{NHR}$) of the substrate (10), which undergoes electron arrangement (11) to produce L-citrulline, $\bullet\text{NO}$, and the ferric resting state (12) [12, 110].

The exact identity of the reactive oxygen intermediate in the conversion of NHA to products is the focus of much experimental investigation. Structures of NHA-bound iNOS [106] impose mechanistic constraints due to steric clash between NHA and the iron-bound dioxygen ligand. This negative interaction favors either free radical addition of the ferric superoxy to the NHA oxime or proton donation from protonated N^ω to the heme species [106]. Furthermore, positioning of the NHA hydroxyl group may direct NOS towards a ferric-peroxo-NHA radical intermediate prior to breakdown into products [106]. However, these structures do not discount participation of a high-valent iron-oxo species in the second half of the reaction. In fact, an iron-oxo would be well situated relative to the NHA oxime to form an oxaziridine (which has a triangular ring with C, N, and O atoms) that could ring-open to produce L-citrulline and $\bullet\text{NO}$ [106]. This type of intermediate has also been proposed to explain the additional products, cyanoornithine and NO^- , observed when the NOS reaction is shunted with peroxide [121]. However, L-citrulline formation in the hydrogen peroxide-dependent oxidation of NHA can be accounted by either mechanism involving a ferric peroxo or an iron-oxo intermediate. Thus, the reaction with hydrogen peroxide cannot be considered to occur exclusively via an iron-oxo intermediate. The lack of cyanoornithine and NO^- under natural turnover conditions favors ferric superoxy over Compound I as the reactive oxygen intermediate when NADPH and O_2 serve as reactants. Recent spectral evidence obtained by Stuehr and coworkers [114] demonstrates that the ferrous oxygenase domain of nNOS can catalyze a quantitative conversion of NHA and dioxygen to citrulline and $\bullet\text{NO}$ in a single turnover reaction. Stopped-flow spectral analysis indicates formation of a ferrous-oxy (or ferric superoxy) species ($\lambda_{\text{max}} = 427 \text{ nm}$) prior to NHA oxidation [116]. Two other groups, using full-length NOS with bound L-Arg [122] or nNOS oxygenase domain with bound N^ω -methyl-L-Arg [123], have observed a ferrous-oxy species that exhibits a considerably more blue-shifted Soret absorption band ($\lambda_{\text{max}} = 415\text{--}419 \text{ nm}$) at -30°C in 50 % ethylene glycol. Examination of the formation and reactivity of the ferric superoxy complex with NHA shows a build-up of the ferric NO species prior to regeneration of the ferric resting state [116]. The accumulation of this intermediate establishes the $\bullet\text{NO}$ radical as the primary product rather than other N-oxides such as nitroxyl, which would generate a ferrous NO complex with the heme. The sum of these studies, while not completely dismissing Compound I as an active participant in catalytic turnover, supports the proposed mechanism shown in Figure 15, indicating that the O–O bond is intact during the NHA oxidation in NADPH-dependent catalysis.

The role of tetrahydrobiopterin

Initially, the role of H₄B in the NOS system appeared to one of dimer stabilization, as indicated by its tight binding at the dimer interface [100–102]. Recent structural and mechanistic investigations have helped to clarify and expand this role, arguing that the cofactor may also participate directly in the NOS catalytic mechanism. Comparison of a series of dihydro- (H₂B) and tetrahydropterins (H₄B) in supporting electron transfer, •NO formation, and dimer formation demonstrates the absolute requirement for reduced pterin for formation of products but not for stable dimer formation [124]. In addition, H₄B decreases the stability of the NOS oxyferrous complex [125], which clearly implies communication between the pterin and heme sites. Studies of dimerization and catalytic competency of H₄B-free iNOS indicate that the pterin is essential for conversion of L-Arg to NHA, but not for conversion of NHA to products [104]. The inability of pterin-free NOS to convert L-Arg to NHA implies a direct catalytic role for H₄B in this portion of the reaction mechanism. Low-temperature, rapid-reaction experiments investigating the effect of H₄B on the decay of the oxyferrous complex of nNOS indicate that the pterin donates an electron to the heme dioxy complex in the presence of L-Arg [122]. Furthermore, recent EPR experiments show the formation of an apparently stable H₃B• radical under single turnover conditions when L-Arg is the substrate [117]. These results, coupled with the known location of the pterin within the crystal structure, are most consistent with H₄B being involved in electron transfer to the heme group in NOS rather than direct interaction with the substrate. The role of H₄B in the conversion of NHA to products is more ambiguous. Pterin-free NOS is still able to convert NHA to L-citrulline and •NO; however, cyanoornithine and NO[−] are also formed [104]. The variation of the product profile in the absence of H₄B implies a role for the pterin in the NHA reaction. A direct redox role is unlikely, as some L-citrulline and •NO are formed. However, the formation of the cyanoornithine and NO[−] products is similar to the effect of shunting NOS with peroxide, indicating that the pterin may play a role in the modulation of the reductive pathway of the ferric superoxy heme complex.

4.4 Heme-Containing Plant Peroxidases

4.4.1 Introduction

Heme peroxidases are found extensively throughout the plant, animal, and bacterial kingdoms. These enzymes catalyze the oxidation of a wide variety of organic and inorganic substrates, with the concomitant reduction of hydrogen peroxide or other hydroperoxides (ROOH) to water to alcohols (ROH), respectively:

Peroxidases fall into two superfamilies (plant and mammalian) and a third, indistinct group that includes chloroperoxidase (a P450-like hybrid) and di-heme cytochrome *c* peroxidase from *Pseudomonas aeruginosa*. The plant peroxidase superfamily contains enzymes of plant, fungal, and bacterial origin [126]. Mammalian peroxidases make up the second superfamily, and include lactoperoxidase, myeloperoxidase, and prostaglandin H synthase. Both families have been the focus of numerous excellent reviews, several of which have discussed the differences between the plant and mammalian peroxidases [126–130]. Here, recent experimental investigations focused on the plant peroxidases will be discussed.

The plant peroxidase superfamily can be further divided into three classes based on sequence and structural similarities [126]. Class I constitutes intracellular peroxidases of prokaryotic origin, such as yeast cytochrome *c* peroxidase (CCP) and pea cytosolic ascorbate peroxidase (APX). The main role of this class of peroxidases appears to be the removal of hydrogen peroxide. Secretory fungal peroxidases such as lignin peroxidase (LIP) and manganese peroxidase (MnP) from *Phanerochate chrysosporium* and *Corpinus* peroxidase (CIP) make up Class II. These enzymes are monomeric glycoproteins, with four conserved disulfide bridges and two conserved calcium sites. The secretory plant peroxidases form Class III. These enzymes are also monomeric glycoproteins, with four conserved disulfide bridges and two conserved calcium sites; however, the location of the disulfide bridges varies from those in Class II enzymes. Enzymes in Class III include peanut peroxidase (PNP), barley grain peroxidase (BP 1), and horseradish peroxidase (HRP), the most thoroughly investigated heme-containing peroxidase.

4.4.2 The Molecular Structure of Heme Peroxidases

In 1980, CCP became the first heme peroxidase to be structurally characterized. Reaction mechanisms, substrate binding sites and ligand interactions were proposed based on the various structures of CCP and carefully applied to the entire plant peroxidase family. During the past decade, a vast number of X-ray crystal structures have been reported for other members of the plant peroxidase superfamily. Presently, structural data are available for members of Class I: CCP [131–137] and APX [138–140]; Class II: MnP [141, 142], LIP [143, 144] and CIP [145]; and Class III: HRP [146–148], PNP [149] and BP 1 [150]. Of the numerous plant peroxidases, Class III members are the most readily available and have been the most extensively studied. The solution of crystal structures of three Class III peroxidases is a recent and exciting development. These structures provide researchers with the structural framework for addressing several mechanistic questions, such as how and where substrates bind to the enzyme, and how the protein controls the location of oxidizing equivalents derived from peroxide. In addition, the availability of structural information for the members of each class gives researchers the first opportunity to compare closely the tertiary environment among members of the same and different classes. This comparative power provides great insight into the relationship between structure and function within the plant peroxidase superfamily.

Figure 17. Schematic representation of the secondary structure of (A) CCP; (B) LIP; and (C) HRP determined from X-ray coordinates [137, 143, 211]. Helical regions, β -sheet regions, and the heme group are shown.

Although there is little sequence homology (often <20 %) within the plant superfamily, the overall folding and organization of the secondary structure is conserved. Figure 17 shows a side-by-side comparison of the secondary and tertiary structure of a representative member of each plant superfamily class. The enzymes are divided into N- and C-terminal domains, with the heme positioned in a cavity at the domain interface. The secondary structure is dominated by α helices (10 to 11 helices) connected by loops and turns of varying lengths. β -sheet structure is minimal. There are nine invariant residues in the plant peroxidase superfamily, five of which are involved in catalysis [128]. The other conserved residues play important structural roles, such as a buried salt bridge between an aspartate and arginine and several glycine and proline residues that direct the orientation of the peptide backbone [126, 129]. Figure 18 shows the active site environment of CCP, LIP, and HRP and the nonvariant residues. The proximal ligand to the heme is a histidine residue that is anionic in nature due to a conserved hydrogen bond to a proximal aspartate residue [128]. On the distal side of the heme, a polar histidine and arginine couple form a hydrophobic cavity above the heme that is important in the stabilization of the bound peroxide and the heterolytic cleavage of the O–O bond [128]. Additionally, an aromatic tryptophan (Class I) or phenylalanine (Class II and III) on the distal side of the heme helps to stabilize the high-valent oxygen intermediates as well as to exclude substrates from the active site. Similarly, a tryptophan (Class I) or phenylalanine (Class II and III) can be found in the proximal cavity and is believed to direct the location of the second oxidizing equivalent of Compound I [128].

In addition to these similarities, there are several distinctions among the plant peroxidases that help to differentiate between catalytic mechanism and substrate

Figure 18. Key catalytic residues for (A) CCP; (B) LIP; and (C) HRP determined from X-ray coordinates [137, 143, 211]. The heme group is coordinated by a histidine and the sixth position is vacant. affinity of the class members. In Class II and III peroxidases, all the cysteine residues in the protein (8 to 10 residues) form disulfide bridges that impart a high degree of rigidity to the protein [129]. Glycosylation sites for the Class II and III peroxidases point away from the molecule and are evenly distributed over the surface of the protein. This scattering suggests that the purpose of the carbohydrates is to increase the solubility of the enzyme in water, and perhaps to increase resistance to free radical-induced protein cross-linking [146].

With the exception of CCP, it is widely accepted that substrates interact with peroxidases at the heme edge rather than above the heme, as seen for the oxygenases. This postulation has been supported by structural and chemical modification data. Chemical modification studies with HRP have shown that the area directly above the heme is inaccessible to exogenous substrates [151–153]. Instead, suicide inhibitors bind at the δ -meso heme carbon (see Figure 1). The structure of HRP in the presence of benzhyroxamic acid (BHA), a model for oxidizing substrates, demonstrates that the aromatic portion of BHA does in fact interact with the proposed aromatic binding region of HRP located at the heme edge [147]. However, BHA is an atypical reducing substrate with unique hydrogen bonding potential for the

active site residues of the distal heme pocket, and therefore may not be an accurate structural model of the peroxidase–substrate complex. Recently, a structure of the HRP–ferulic acid (FA) complex in the presence and absence of cyanide has been published [148]. As FA is known to act as an *in vivo* substrate for peroxidases [148], these structures may provide a more precise model for the oxidation of small phenolic complexes by a plant peroxidase. Similar to BHA, FA binds in the aromatic binding pocket, but its exact orientation is ambiguous due to a flexibility of the aromatic donor binding region. This flexibility allows for the fast exchange of solvent molecules and small phenolic compounds, thereby protecting the heme group from autooxidative damage by the radical product of catalytic turnover [148]. Addition of cyanide to the system yields a six-coordinate low-spin heme complex that is thought structurally to model the transient intermediate ($\text{Fe}^{3+}\text{--OOH}^-$) prior to Compound I formation. Comparison of the structures of this ternary complex (HRP–FA–CN) with those of native HRP, the HRP–BHA and the HRP–FA species illustrates movement of the distal histidine 0.5 Å towards the cyanide nitrogen, thus supplying a short hydrogen bond to stabilize the binding of the ligand. The distal arginine does not move in any of the structures, but does help to stabilize cyanide by forming a hydrogen bond to the cyanide nitrogen [148]. This stabilization role for the distal arginine may imply that the residue assists in heterolytic bond cleavage by acting as a hydrogen bond donor to the transient $\text{Fe}^{3+}\text{--OOH}^-$ complex [148]. Similar to HRP, both APX and MnP have been shown to interact with their respective substrates at the heme edge rather than above the prosthetic group [139, 141, 142].

As the peroxidases interact with their substrates via the heme edge, it is important that the oxidizing equivalents of the high-valent active oxygen intermediates are accessible to the substrates. To this end, two calcium-binding sites—one distal and one proximal to the heme—serve dual structural and catalytic roles for the Class II and III proteins [127–129]. The distal site is important in the ordering of the distal active site residues, particularly the catalytically active histidine [127]. The proximal cation is responsible for structural stability, as well as promoting the location of the second oxidizing equivalent on the porphyrin macrocycle rather than a protein residue [127]. APX, a Class I peroxidase, contains a single cation binding site on the proximal side of the heme occupied by a potassium ion [138]. The cation destabilizes the electrostatic environment surrounding the proximal tryptophan involved in hydrogen bonding interactions with the proximal histidine ligand and the nearby aspartate (Figure 19). This long-range electrostatic effect forces the second oxidizing equivalent of Compound I to remain on the heme macrocycle, ideally positioned for reactions at the heme edge [154]. CCP, also a Class I peroxidase, interacts with its natural substrate, cytochrome *c*, not at the heme edge but via an electron transfer pathway that begins at Trp191 and terminates at the protein surface (Figure 20). As a result, CCP has no bound cations and maintains a stable cation radical on the indole ring of Trp191 rather than the porphyrin during catalytic turnover [137]. The continuing accumulation of structural information for plant peroxidases will allow the key similarities and differences to be exploited through mutagenesis to explore the physiochemical differences between members of the plant superfamily.

4.4.3 The Catalytic Mechanism of Heme Peroxidases

The general peroxidase mechanism

Following the determination of the crystal structure of CCP, a catalytic mechanism for its reaction with hydrogen peroxide was proposed [131, 136]. Due to the conservation of the active site residues in the plant peroxidase superfamily, similar mechanisms of Compound I formation are also thought to hold for other plant and fungal peroxidases. Of the structures shown schematically in Figure 21, three have been spectroscopically, and structurally characterized while two are proposed intermediates. The pathway is initiated by the direct reaction of neutral hydroperoxides (ROOH) or hydrogen peroxide with the ferric five-coordinate high-spin resting state complex (**1**) to generate a transient hydroperoxide adduct termed Compound 0 (**2**). Formation of this intermediate species is postulated by theoretical molecular dynamic simulations [155] and density functional studies [156], as well as being observed for HRP at low temperature [157]. This intermediate species then undergoes a protein-assisted conversion to an oxywater complex (**3**) [155, 156]. Facile heterolytic O–O bond cleavage of this oxywater complex yields the high-valent active oxygen intermediate, Compound I (**4**). For the majority of peroxidases

Figure 20. (A) Ribbon drawing of the interaction between CCP and its redox substrate, cytochrome *c* determined from X-ray coordinates [137]. The hemes are shown for CCP and cytochrome *c* along with the proximal residues involved in electron transport between the proteins. (B) A close-up of the electron transport chain and their overlapping electron density.

this complex is an oxo-ferryl species with a porphyrin cation radical similar to the Compound I seen in the P450 catalytic cycle (see Figure 4, complex 7). In CCP, the second oxidizing equivalent is intramolecularly transferred from the porphyrin to proximal Trp191 residue (Figure 18A), yielding a stable complex with a protein cation radical coupled with an oxo-ferryl heme [158, 159]. Reduction of Compound I to Compound II (5), an oxo-ferryl complex, and then to the ferric resting state, occurs with concomitant one-electron substrate oxidation forming reactive transient radical species that may dimerize, disproportionate, or attack another species causing cooxidation. Alternatively, oxygen atom donors can be added to the ferric resting state to generate Compound I, via a shunt pathway similar to that seen for P450 enzymes.

Influence of the active site environment on heme coordination and reactivity

The distal cavity

Extensive crystallographic and mutagenic studies have identified the key catalytic residues important in the formation and stabilization of the active oxygen intermediates. On the distal side of the heme, the conserved distal arginine/histidine couple is vital to efficient catalytic turnover by stabilizing and heterolytically cleaving bound peroxide to form the high-valent intermediate, Compound I (see Figure 7) [128]. The distal histidine acts as a general acid–base catalyst in the reaction of a

Figure 21. Peroxidase reaction cycle. AH represents the oxidizable substrate, and •A is the product. See text for details.

peroxidase with hydrogen peroxide by first deprotonating the iron-bound oxygen of peroxide (Figure 21, 2) then transferring the proton to the outer oxygen (Figure 21, 3) [128]. Deletion of this residue in both CCP (H52L) and HRP (H42A and H42V) results in the drastic reduction of the rate of Compound I formation by five orders of magnitude [160, 161]. This decrease in activity is presumably due to the elimination of a critical acid–base catalyst from the active site. Interestingly, activity of the H42A HRP mutant is restored by the addition of exogenous 2-substituted imidazoles (H42A + imidazole) [162]. Bronstead analysis predicts that ~60 % of a positive charge develops on the imidazole in the transition state of Compound I formation [162], confirming the acid–base role of the distal histidine.

Surprisingly, conversion of His42 of HRP to a glutamate [163], a residue shown to participate in general acid–base chemistry in chloroperoxidase (CPO) [164], yields an enzyme with lowered rates of Compound I formation and lowered levels of peroxidase activity [163]. In CPO, Compound I is formed at a rate ($2.3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) [165] much higher than H42E HRP ($4.9 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$) and comparable to wild-type HRP ($1.4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) [163]. The inefficient formation of Compound I is likely due to a decrease in the basicity of the glutamate residue and its improper orientation in H42E HRP compared to that of the native histidine. These alterations in the distal pocket destabilize the heme-peroxide-Glu42 ternary intermediate of the peroxide reaction [163]. The crystal structure of CPO shows that the distal

Glu is fixed in position by a hydrogen bond with an adjacent histidine [164]. Similarly, the orientation and basicity of the distal histidine in the plant peroxidases appears to be maintained by conserved hydrogen bonding interactions between the catalytic histidine and a highly conserved asparagine residue (see Figure 18). In HRP, mutation of this asparagine (Asn70) to valine (N70V) abolishes its hydrogen-bonding capabilities, causing a decrease in the rate of Compound I formation [166, 167]. Further studies reveal that its replacement with an aspartate (N70D) yields a mutant that should maintain the hydrogen bond with His42 but is still inactive [168]. Inactivation of HRP is likely due to the loss of a second hydrogen bonding interaction between Asp70 and the backbone carbonyl of a conserved glutamate residue (Glu64; Figure 18C). The disruption of this secondary interaction alters the orientation of the aspartate with regard to His42, resulting in the breakage of the Asp70–His42 hydrogen bond [168]. These findings demonstrate the manner by which the active site environment of the plant peroxidases has evolved to stabilize and promote the distal histidine as an active participant in the formation and stabilization of Compound I.

In contrast, the distal arginine residue does not appear to be absolutely essential in the formation of Compound I. In the mechanism proposed by Poulos et al. [131], the positively charged distal arginine is responsible for the promotion of O–O bond heterolysis by stabilizing the precursor enzyme–peroxide complex. Consistent with this proposed role, mutation of this polar residue to a neutral leucine in HRP (R38L) and CCP (R48L) causes a decrease in the rate of Compound I formation, particularly in the HRP mutants [169–173]. The reasoning for this variation of mutagenic effect stems from the increased polarity of the CCP distal pocket compared to that of HRP. As a result, the deletion of the distal arginine in CCP does not cause as drastic an effect on the ability of the enzyme to form Compound I [170, 171]. Moreover, the recently demonstrated crystal structure of HRP with ferulic acid and cyanide bound indicates that the distal arginine does indeed stabilize the bound ligand through hydrogen-bonding interactions [148].

Additional experiments with R38L HRP indicate that Arg38 may also play an important role in the binding of peroxide to the heme iron [171]. Researchers propose that the polar character of Arg38 in HRP facilitates the access of hydrogen peroxide to the heme and/or provides an electrostatic interaction with the incoming peroxide, which may induce the deprotonation of hydrogen peroxide at neutral pH [171]. Additionally, the reaction of H38L HRP with hydrogen peroxide results in the accumulation of a previously unseen intermediate formed prior to Compound I formation [171]. The spectroscopic properties of this complex are dissimilar from those of the proposed ferric peroxy intermediate (Figure 21, 2) isolated at low temperature for the reaction of wild-type HRP with peroxide [157]. Theoretical molecular modeling studies assign the new spectral intermediate to a neutral peroxide-bound ferric heme species [174].

In both peroxidases, the decay of Compound I is drastically increased by the deletion of the distal arginine, emphasizing its role as a stabilizer of the high-valent intermediate [169–171, 173, 175]. Crystallographic and resonance Raman data have shown that the distal arginine is very flexible, and can move towards or away from the ligand in the sixth position as needed [135, 176]. This flexibility allows the gua-

nitidinium groups to move inside the cavity and form a stabilizing hydrogen bond with the ferryl oxygen atom of Compound I and II [134].

The proximal cavity

Crystal structure data from representatives of each of the three classes of the plant peroxidase superfamily confirm that the side chain of an aspartate residue is involved in a key hydrogen bond to the N δ 1H of the proximal histidine residue (see Figure 18) [128, 146]. The purpose of this residue has been most investigated for CCP where the carboxylate side chain of Asp235 is involved in hydrogen bonds with both Trp191 and the proximal His175 ligand (Figure 18A). Using the wild-type enzyme and three CCP mutants (D235A, D235E, and D235N), three main roles have been proposed for this residue based on extensive spectroscopic characterization [71, 177]. First, the strong hydrogen bond from the proximal His to the adjacent Asp is believed to increase the electron density on the histidine imidazole ring, which in turn allows the imidazole group to stabilize the heme iron as it cycles through ferric and ferryl states during the catalytic cycle [71, 177]. Second, the strong hydrogen bond is believed to hold the iron below the heme plane, helping to maintain a vacant sixth coordination site [178]. Finally, the formation of a second hydrogen bond with the catalytically important Trp191 optimizes the orientation of the Trp side chain with respect to the heme and His175. Interestingly, the D235N CCP only showed a five-fold decrease in the rate of formation of Compound I [71] while the D235A CCP mutant rapidly forms Compound I [177]. These results demonstrate that the electronic donation to the heme iron via His175 does not significantly increase Compound I formation, indicating that Asp235 is not especially important for the reaction of the peroxidase with hydrogen peroxide. Recent mutagenic studies on CIP (D245N) and MnP (D242S and D242E) (two Class II peroxidases) confirm that changes in the axial ligand hydrogen-bonding network alter the occupancy of the sixth coordination site for the ferric protein as well as the reactivity of Compound II but not Compound I [179–181]. Similarly, mutation of the proximal ligand itself (His175) to Gln, Glu, or Cys results in CCP mutants that react with hydrogen peroxide as fast as wild-type CCP with the H175E mutant being hyperactive [182, 183]. Taken together, these data emphasize the importance of the distal rather than the proximal residues in the formation of Compound I. However, the proximal environment serves the equally significant roles of maintaining a free sixth coordination site for hydrogen peroxide binding and stabilizing Compound I once formed.

The role of the divalent cations in Class II and III peroxidases

All Class II and III plant peroxidases have two calcium binding sites, one proximal and one distal to the heme plane (see Figure 18B and C). These divalent cations appear to be vital for efficient peroxide catalysis by maintaining the structural integrity of the heme active site and directing the location of the second oxidizing equivalent derived from peroxide. A series of mutagenic studies with LIP and MnP ascertain that the calcium ions for these two peroxidases are released upon thermal inactivation [184–186]. The loss of these ions results in perturbations of the coordi-

nation sphere of the heme iron. LIP converts from an active five-coordinate high-spin complex to a mixture of active five-coordinate high-spin and inactive six-coordinate low-spin species [184]. The heme environment of MnP is particularly altered, resulting in an inactive six-coordinate low-spin complex with spectroscopic characteristics consistent with bis-histidyl ligation [185, 186]. In HRP, mutation of Glu64—a residue involved in both calcium binding and a hydrogen-bonding network with His42—gives an enzyme with significantly decreased oxidation activities [187]. This decrease in activity is attributed to the loss of the distal calcium ion, which causes the reorientation of both His42 and Arg38 [187].

APX contains a single cation binding site occupied by a potassium ion (see Figure 20) [138, 140]. This site is not seen for CCP, implicating the cation in the catalytic mechanism or regulation of APX. Similar to CCP, APX has an aromatic tryptophan on the proximal side of the heme that forms hydrogen bonds with both the proximal histidine ligand and the nearby aspartate (Figure 19) [138, 140]. In CCP, the analogous tryptophan is the location of the second oxidizing equivalent of Compound I. However, in APX, this equivalent is located on the porphyrin, similar to the Class II and III peroxidases [128, 154, 188]. Incorporation of a cation binding site into CCP results in an enzyme that is unable to form a stable cation radical on the proximal tryptophan. These results suggest that long-range electrostatic effects can control the reactivity of a redox amino acid side chain [189–191]. A similar result is seen for a mutant of HRP where the redox inactive proximal phenylalanine is replaced with a tryptophan (F221W). In this case, an unstable tryptophan cation radical is formed upon reaction with peroxide, but quickly dissipates into the protein matrix due to the improper orientation of the indole ring and its proximity to the proximal calcium ion [192]. Deletion of the cation site in APX results in an inactive six-coordinate low-spin species with spectroscopic similarity to a bis-histidyl complex [193]. Despite being located ~ 8 Å from the peroxide binding site, mutation of residues involved in binding of the potassium ion results in long-range conformational alterations [193]. Taken together, these studies emphasize the role the proximal cation plays in the both location of the oxidizing equivalents of Compound I, as well as in the preservation of the structural integrity of the heme active site.

4.4.4 Can Peroxidases Catalyze Peroxygenase Chemistry?

With resemblance of the active intermediates of their respective mechanistic cycles, it is somewhat surprising that peroxidase and monooxygenases do not catalyze similar reactions. Investigations by Ortiz de Montellano and coworkers have shown that the extent of protein surface exposure of the heme macrocycle for peroxidases and P450s plays an important role in the discretion of function of the enzyme [152, 153, 194]. Examination of reactions of HRP and P450CAM with alkyl- and phenylhydrazines shows that the hydrazine interacts with the iron of the monooxygenase, but is limited to the heme edge of the peroxidase [151–153]. Various distal side mutations in HRP have been made in an effort to maintain catalytic efficiency while opening up the distal cavity [162, 195]. Enhanced oxygenase activity

of HRP mutants such as F41A [161], H42A [161], H42E [163], and the two double mutants, F41H/H42A [195] and H42A/R38H [127] is the direct result of increasing substrate accessibility to the oxo-iron of Compound I. These results support the current hypothesis that the reactivity of the heme prosthetic group depends not only on the coordination of the heme iron itself but also on the topology of the protein surrounding it.

4.4.5 Development of CCP as a Protein Model System for Heme-Containing Enzymes

Complementary to the studies of native proteins and synthetic model systems, site-directed mutagenesis allows researchers rationally to design structural and catalytic mimics for different heme proteins from basic protein scaffolding such as CCP. This technique enables the researcher to alter the axial ligation of the protein in order to test principles obtained from earlier studies on the native protein, and to determine key structural features governing the discretion among protein functions. In the area of P450 models, this technique has been utilized to replace the histidine proximal ligand of CCP with a cysteine in order to engineer a P450-like protein in a peroxidase protein environment [183, 196]. Peroxidase and P450 enzymes have similar proposed reaction intermediates (e.g., Compounds I and II), though the lifetime and reactivity of those intermediates vary. As the main difference between a peroxidase and a P450 protein is the ratio of electron transfer to oxygenation, or the branching ratio, the catalytic differences between CCP and P450 are quite subtle. Initial attempts to place a cysteine ligand into a peroxidase environment were not successful [181]. Poulos and coworkers mutated the proximal His175 of CCP to Cys, but this did not result in thiolate ligation to the heme [183]. Instead, they determined by X-ray crystallography that the proximal Cys had been oxidized to cysteic acid [183]. It was suggested that this had occurred due to the smaller size of Cys relative to His, presumably leaving the Cys too far from the heme iron to bind properly, and thus susceptible to oxidation. Recent work by Lu, Dawson and co-workers indicates that the negative charge of the proximal Asp235 residue of CCP conflicts with the negative charge of the mutated thiolate ligand [196]. Replacement of Asp235 with a leucine residue resulted in a double mutant of CCP (H175C/D235L) which has UV-visible, magnetic circular dichroism and EPR spectral characteristics that are similar to those of camphor-bound P450 [196], indicating the potential of this system as a model for P450 enzymes.

Rational design has also been utilized to engineer artificial metal binding sites into CCP in an effort to mimic the active sites of MnP (a heme and manganese ion center), cytochrome *c* oxidase (COX, a heme and Cu_B center) and the potassium-binding site of APX. In the case of the MnP mimic, creation of a manganese binding site near the heme of CCP results in a model system which binds a single manganese ion, reacts with hydrogen peroxidase to form Compound I, and catalyzes the steady state oxidation of Mn²⁺ at enhanced rates compared to wild-type CCP [197–199]. In an effort to improve the MnP model, the two active site tryptophan residues (Trp191 and Trp51) of CCP have been mutated to their MnP-analogous phenyl-

alanine residues [200]. The results of this study demonstrate that, while the W191F and W51F mutations both play important roles in stabilizing Compound I, only the W51F mutation contributes significantly to increasing the MnP activity [200]. This effect is attributed to the ability of this mutation to increase the reactivity of Compound II, whose oxidation of Mn^{2+} is the rate-determining step in the reaction mechanism [200]. Preliminary results for the COX mimic indicate the successful binding of a copper ion above the heme plane of CCP upon mutation of three distal residues to histidines (R48H, W51H, and S81H) [201]. EPR studies of this CCP mutant strongly suggest that the heme Fe(III) is antiferromagnetically coupled to the added Cu(II) similar to the case in the Cu_B -heme center in all terminal oxidases [201]. Design of a proximal cation binding site similar to that seen for APX and the Class II and III plant peroxidases has also been accomplished for CCP [190, 191]. As expected, insertion of a potassium ion on the proximal side of CCP heme increases the electrostatic potential surrounding Trp191, and the proximal environment is no longer able to effectively stabilize a cationic Trp radical [190, 191]. In an extension of this work, slight alteration of the CCP template that binds potassium results in a CCP mutant that can bind a calcium ion [189]. Similar to the potassium-bound CCP, the cation decreases the stability of the Trp191 cation radical during hydrogen peroxide turnover [189]. The engineering of these varied metal-binding sites yields a deeper understanding for the structural factors that control metal-binding site selectivity.

In a departure from designing artificial metal-binding sites within CCP, recent attention has focused on replacing bulky amino acids with smaller residues such as glycine or alanine to form artificial cavities within the protein environment. Termed cavity mutants, these proteins have the unique ability to bind exogenous ligands either to reconstitute their wild-type activity or to catalyze an unnatural reaction. Initially, this approach focused on the deletion of the proximal ligand and the titration of different exogenous ligands into the proximal cavity in an effort to rescue the catalytic activity of the protein (Figure 22). Pioneered by Barrick for sperm whale myoglobin [202], this method has since been accomplished for CCP [203], heme oxygenase [204], and HRP [205]. For H175G CCP, studies to date have focused on the dynamics of binding unnatural ligands and the resulting effects on catalytic activity. Crystallographic analysis of H175G CCP in the presence of exogenous imidazole shows that the imidazole ligand occupies the same position as the natural histidine, and that there is little deviation in the protein structure [203]. Surprisingly, the imidazole-reconstituted system is devoid of activity despite the binding of the imidazole to the heme in the proximal pocket [203]. An oxo-ferryl species has been generated, although more slowly than for the wild-type [203]. Solid-state deuterium NMR studies investigated whether the unfettering of the proximal ligand from the protein enables it to adopt varied conformations or energetics that alter the pathway or interaction with hydrogen peroxide [206]. No evidence for intermediate ring flipping exchange dynamics or for large angular librations of the ring is observed [206]. Thus, the absence of enzymatic activity is not due to a disordered state for the untethered imidazole.

In an effort to introduce novel substrate oxidation into CCP, the catalytically important Trp191 is replaced with a glycine residue, forming a cavity on the prox-

Figure 22. Schematic representation of the active sites of wild-type CCP and the CCP cavity mutant (H175G). Exogenous ligands can be titrated in, or dialyzed out of, the cavity.

imal side of the heme. This buried cavity is able to bind a range of small cationic imidazoles [207], illustrating its ability to stabilize molecules with positive charge. Similar to the imidazoles, 2-aminothiazole (2AT) will also bind within the cavity, as evidenced by calorimetric and crystallographic results [208]. Two separate reactions are observed between 2AT and the oxidized centers of W191G CCP. First, EPR and optical spectra show that 2AT acts as an electron donor to the ferryl center of W191G CCP to reduce it back to the ferric resting state [208]. Second, a less efficient reaction between 2AT and W191G CCP results in the specific covalent modification of Tyr236 [208]. This unexpected result provides the specific assignment of Tyr236 as the site of the alternate radical center when Trp191 is unavailable [208].

Recently, a cavity has been engineered into the distal cavity in an attempt to mimic the oxygenase activity of NOS. Crystallographic and optical studies show that the mutation of Arg48 to an alanine yields a cavity capable of binding *N*^ω-hydroxy-L-arginine (NHA) and *N*-hydroxyguanidine (NHG) [209]. Compound I formation is retained, with as many as three products being observed from the R48A/peroxide-catalyzed oxidation of NHA and NHG [209]. Characterization by mass-spectrometry of the derivatized products of NHA oxidation identified a yellow species as *N*-nitrosoarginine, thus implicating *N*-nitrosoguanidine as the product of NHG oxidation [209]. Therefore, while the hydrogen peroxide-dependent chemistry

catalyzed by R48A CCP has some features in common with that of NOS, namely the ability to oxidize *N*-hydroxyguanidines but not guanidines, the reaction products are clearly distinct from those previously reported for NOS (i.e., cyanamide or N^δ -cyanoornithine) [209].

4.5 Conclusions

The relationship between protein structure and function is an area of continuously growing knowledge, as well as problems. The various mechanisms by which oxygenases and peroxidases accomplish their respective reactions are a testament to the reactive versatility of the heme prosthetic group. For P450 enzymes, emerging crystallographic and mechanistic information is moving this field of biochemical research in new and exciting directions. With the growing understanding of how these enzymes interact with their respective substrates, redox partners and—in some cases—the membrane, the rational engineering of P450s may not be far away. Such a stride will enable researchers to tailor this versatile monooxygenase toward specific, biologically active compounds involved in both positive and negative physiological process. In the newer field of NOS research, the recent availability of structural data for two of the three NOS isoforms has helped to create a clearer picture of how this monooxygenase discriminates between active oxygen intermediates in its catalytic mechanism. Presently, mechanistic and mutagenic studies designed to test structure-based proposals are clarifying the role of the heme prosthetic group and the tetrahydrobiopterin in the efficient biosynthesis of nitric oxide. Finally, the recent addition of the crystal structure of HRP to the growing body of structural information on the plant peroxidase superfamily has enabled researchers to compare and contrast the secondary make-up of these versatile oxidases. The roles of many of the catalytic residues conserved across the three classes are now well understood—the result of exhaustive mutagenic and crystallographic studies. The exploitation of CCP as a protein scaffold for the engineering of novel activities and metal binding sites into a peroxidase environment now offers a biological alternative to inorganic model chemistry. The investigation and expansion of this application of rational protein design provides researchers with an opportunity to investigate the structure–function relationships in heme-containing enzymes that differentiate their catalytic activities.

FA	C-ferulic acid
CN	cyanide
COX	cytochrome <i>c</i> oxidase
2AT	2-aminothiazole
NHG	<i>N</i> -hydroxyguanidine

5 Electron Transfer and Charge Transport Processes in DNA

Frederick D. Lewis

5.1 Introduction

5.1.1 Background

The nucleic acids DNA and RNA are biopolymers with several essential biological functions, including the storage and transport of genetic information [1, 2]. They are constructed from relatively simple building blocks consisting of a pendant heterocycle (nucleobase) covalently attached to a backbone consisting of an alternating sugar-phosphate copolymer. Single-strand DNA and RNA can exist in a variety of secondary and tertiary structures. Cellular DNA exists predominantly as a duplex in which hydrogen-bonded base pairs form extended one-dimensional π -stacked arrays (see Section 5.1.2). This highly ordered structure is found nowhere else in nature, and thus has a special fascination for both biologist and chemists. Materials chemists have recently exploited the unique structural properties of the nucleic acids to prepare an amazing variety of two- and three-dimensional nanostructures [3]. The advent of molecular electronics has stimulated interest in molecular technologies based on DNA [4]. The use of DNA as a data carrier also provides the conceptual basis for DNA-based computing [5].

The nucleic acids can be oxidized by chemical and photochemical oxidants and by ionizing radiation [6–9]. Oxidation can result in strand cleavage, leading to loss or mutation of the genetic information carried by DNA or RNA and can lead in turn to cell death. Damage to duplex DNA is the most important effect of ionizing radiation upon the living cell, and thus has been the subject of extensive investigation by radiation biologists [9]. Oxidative cleavage of duplex DNA is observed to be site-selective, occurring predominantly at guanine-containing sites, particularly those with two or three adjacent guanines in the same strand. Since radiation can ionize all of the nucleobases, charge migration from the initial site of oxidation to the site of cleavage must occur. Understanding the nature of the charge migration process is thus essential to understand oxidative damage to DNA. The possibility

that the π -stacked nucleobases of duplex DNA might serve as a conduit or “ π -way” for electron transport was suggested by Eley and Spivey [10] in 1962, based on their studies of conductivity in dry samples of DNA and RNA.

During the past decade, photochemical methods have been widely used to investigate electron transfer processes in DNA [11–15]. Three distinct types of photo-induced electron transfer processes have been identified:

- 1) The direct electron transfer process between an excited molecule and nucleobase which occur either upon collision or excitation of a ground-state complex. Studies of this processes have helped define the energetic and geometric requirements for nucleobase oxidation and reduction.
- 2) A single-step electron transfer process between an excited molecule and ground-state molecule separated by a variable number of base pairs, DNA-mediated electron transfer. The possible occurrence of wire-like behavior in DNA has generated considerable controversy and the attention of the popular science press [16].
- 3) Charge transport, a process in which a cation radical (hole) generated at a specific site can migrate over long distances in DNA to a trap site where strand cleavage may occur [17].

Several recent reviews have dealt with specific aspects of the photoinduced electron-transfer process in DNA, including photoinduced cleavage and the distance dependence of electron transfer processes [6, 11–15]. Most of these have dealt mainly with a specific class of photooxidizing agents, transition metal complexes. Numerous shorter polemics either defending or attacking the “molecular wire” paradigm have also appeared [18]. The objective of this review is to present the current status of experimental and theoretical work on photoinduced electron transfer and charge transport processes in DNA. Emphasis will be placed on experiments which provide information about the dynamics of these processes either by direct spectroscopic measurements or indirect measurements of strand cleavage efficiency. The introduction is intended to provide a background for the nonexpert in the structure and properties of DNA and studies of its direct ionization. The following sections treat the three classes of photoinduced electron transfer described in the preceding paragraph and studies of DNA conductivity.

5.1.2 Structure and Properties of DNA

DNA structure

The primary structure of an oligonucleotide containing the four common deoxyribonucleotides found in DNA is shown in Figure 1a [19]. Each deoxyribonucleotide consists of three parts; a negatively charged phosphate, the sugar 2'-deoxyribose, and the heterocyclic nucleobase. The bases cytosine (C) and thymine (T) are derivatives of pyrimidine which has a single aromatic ring, whereas the bases adenine (A) and guanine (G) are derivatives of purine which has two fused aromatic rings.

Figure 1. (a) The structure of an oligonucleotide composed of the four naturally occurring nucleobases adenine (A), guanine (G), cytosine (C), and thymine (T). (b) The structures of nucleobase analogues employed in electron transfer studies, and abbreviations used in this chapter.

A nucleotide lacking its phosphate is called a nucleoside, and a nucleoside lacking a sugar is called a nucleobase or base. The primary structure of RNA differs from that of DNA in that the sugar is ribose rather than 2'-deoxyribose and the pyrimidine thymine is replaced by uracil (U). In both DNA and RNA the phosphate group connects the 5' position of one ribose with the 3' position of the next. Thus, the oligonucleotide has a 5' → 3' polarity. Chemical modifications of the five common nucleobases are frequently encountered, particularly in RNA. The structures of several modified bases which have been employed in investigations of electron transfer process are shown in Figure 1b.

Under physiological conditions DNA exists predominantly as a duplex formed between complementary anti-parallel strands of DNA in which the purines of one strand are hydrogen bonded to the pyrimidines of the complementary strand and vice versa to form G:C and A:T base pairs. The Watson-Crick G:C base pairs (Figure 2) possess three hydrogen bonds and the A:T base pairs two hydrogen bonds, each hydrogen bond contributing approximately 2 kcal mol^{-1} to the stabil-

Figure 2. Base pairing in Watson–Crick C:G and T:A base pairs.

ity of the duplex. Duplex DNA can adopt one of several secondary structures, the most common of which is termed B-form DNA. B-form DNA adopts a right-hand helical structure (Figure 3) in which the hydrophobic base pairs form a π -stacked array perpendicular to the helical axis, with a stacking distance of 3.4 Å [20]. Base stacking is energetically favorable, making a substantial contribution to the thermodynamic stability of B-form DNA. The two hydrophilic sugar-phosphate backbones lie on the outside of the helix, creating two grooves of similar depth but different widths, known as the major and minor grooves. A complete helical turn occurs every ten base pairs, and thus each base pair is rotated by approximately 36° with respect to its neighbor.

Most studies of DNA-mediated electron transfer and charge transport have employed B-form DNA. However, duplex or double-strand (ds) DNA can adopt other

Figure 3. Structure of a B-form DNA 12-base pair duplex [20].

structures including A-form and Z-form DNA. In addition, higher-order triplex and quadruplex structures are stable under certain conditions. Local structures are dependent upon the base sequence. For example, poly-A:poly-T regions favor B-form local structures, whereas poly-G:poly-C regions favor A-form local structures. The B-form structure can also be distorted by base-pair mismatches (e.g., a G:T base pair), a missing base (abasic site), or one or more “extra” bases, which result in formation of a bulge in one strand of the duplex. For the purposes of this discussion, it will be assumed that duplex DNA adopts an idealized B-form structure except when otherwise noted.

Crystal structures of B-form DNA can give a misleading impression of structural rigidity. A recent report of the crystal structure of a 6-mer complex of daunomycin with 1.1 Å resolution at 100 K revealed that the phosphates and ribose can adopt two or more distinct conformations, even at low temperature in the solid state [21]. Experimental and theoretical studies indicate that the duplex sugar-phosphate backbone undergoes conformational changes on a time-scale of 20–200 ps, but that base pair hydrogen bonds remain intact on this time scale [22]. A recent investigation of the dynamic Stokes shift of a duplex containing a fluorescent base-pair analogue found the interior of DNA undergoes geometry changes on slower time scales (300 ps and 13 ns) [22d].

RNA exists predominantly as a single strand possessing highly varied and complex secondary structures [1–3, 19]. These include regions of intra-strand base pairs connected by loops and junctions. Single-strand (ss) DNA also has a complex secondary structure with regions of local base stacking and loop regions formed by intra-strand base-pairing. While this structural diversity is in some ways analogous to that present in proteins, the availability of crystal structures for proteins has made possible the investigation of the distance and pathway dependence of long-range electron transfer. However, studies of bridge-mediated electron transfer in RNA or single-strand DNA are complicated by the lack of structural information.

Investigations of electron transfer and charge transport processes in ds DNA have involved a variety of organic and inorganic probe molecules which can interact with the duplex structure in different ways. For example, metal ions can form inner- and outer sphere complexes with one or more nucleobase lone pairs in the major or minor groove. Planar aromatic molecules can intercalate between two adjacent base pairs. Intercalation results in perturbation of the duplex structure to accommodate the intercalated molecule, most notably an unwinding of the double-helical structure. A crystal structure of the self-complementary duplex d(CGTAACG) with two intercalated anthraquinone derivatives is shown in Figure 4 [23]. The anthraquinone is fully intercalated with its pendant aminoalkyl groups located in the major groove. Intercalation leads to unwinding and stiffening of the helix, which can result in decreased rates of base dynamic motion [24]. Planar aromatic molecules can also form π -stacked complexes with the external base-pair, a so-called end-stacked geometry [25]. The author's laboratory has employed hairpin-forming *bis*-oligonucleotide conjugates with aromatic linkers in their studies of electron transfer dynamics. The structure of a stilbenediether-linked hairpin is shown in Figure 5 [26]. The six base pairs adopt a normal B-form duplex structure with the stilbene π -stacked with the adjacent base pair. Metallointercalators have been ex-

Figure 4. Structure of a 6-mer duplex with two intercalated anthraquinone derivatives shown with cylindrical bonds [23].

tensively employed in studies of DNA electron transfer processes [11–15]. The crystal structure of a rhodium complex intercalated into DNA has recently been published [see Addendum].

Electronic spectra

The individual nucleobases, nucleosides, and nucleotides all have broad absorption bands with maxima near 260 nm [8]. These bands result from overlapping $n \rightarrow \pi^*$

Figure 5. Structure of a stilbene diether-linked hairpin. The linker is shown at top of structure with cylindrical bonds [26].

and $\pi \rightarrow \pi^*$ transitions. An indication of the complexity of the nucleobase electronic spectra is provided by a recent study of the electronic transitions in the adenine derivatives 7-methyl and 9-methyladenine for which the near-UV spectrum was resolved into five moderately strong $\pi \rightarrow \pi^*$ transitions and a single weak $n \rightarrow \pi^*$ transition [27]. Stacking of the nucleobases in B-form duplex DNA results in a c. 20–25 % decrease in the 260-nm absorbance compared to that of the single-strand DNA, a phenomenon known as hypochromism [28]. The observation of hypochromism provides a simple diagnostic for the duplex formation upon hybridization of complementary strands. B-form DNA also has a characteristic circular dichroism spectrum, with a positive band near 280 nm and a negative band near 250 nm, which is distinct from those for A-form and Z-form DNA [27]. Neither the natural nucleobases nor oligonucleotides absorb at wavelengths longer than 300 nm. Thus, selective excitation of probe chromophores in the presence of a large excess of DNA is possible using wavelengths >300 nm.

The naturally occurring nucleobases, nucleosides, and nucleotides are all very weakly fluorescent, with singlet lifetimes <20 ps and fluorescence quantum yields $<5 \times 10^{-4}$ [8]. Even weaker fluorescence is observed for duplex DNA. The nucleobase singlet energies, as determined from the $0,0'$ singlet state transitions, all lie between 285 and 300 nm, guanine having the lowest singlet energy and adenine the highest [8]. Intersystem crossing quantum yields for the nucleobases, nucleosides, and nucleotides are also low ($<10^{-2}$). Thus, the singlet states decay predominantly by nonradiative processes which occur with rate constants of approximately 10^{12} s^{-1} . Rapid nonradiative decay may help minimize photochemical damage to cellular DNA by ultraviolet radiation. The short singlet lifetimes and low intersystem crossing yields also preclude the use of the singlet nucleobases as excited state donors or acceptors in studies of photoinduced electron transfer.

Fluorescent nucleobase analogues have been employed as probes of DNA structure and dynamics. Among these are 2-aminopurine (AP) [29, 30] and 1, N^6 -ethanoadenine (EAD) [30, 31] (see Figure 1b). AP and EAD have absorption maxima at 305 and 294 nm, respectively, and absorb at wavelengths longer than 300 nm where the natural nucleobases do not absorb. AP and EAD have been incorporated into synthetic oligonucleotides. When base-paired with T, AP adopts a normal π -stacked B-form DNA structure. Due to its large size, EA stacks poorly in the duplex. Unlike A which is very weakly fluorescent, both AP and EAD are strongly fluorescent with quantum yields of 0.68 and 0.56, respectively, for the nucleoside in aqueous solution at pH 7.0. The fluorescence decay times for the nucleosides in water are 10.4 ns for AP and 23.8 ns for EAD, respectively. The fluorescence of EAD is partially quenched upon incorporation into DNA [30, 31]. The fluorescence of AP is strongly quenched upon incorporation of AP into DNA, and its fluorescence decay becomes a complex multi-exponential function [29, 30].

Ionization potentials and electron affinities

The gas phase ionization potentials (IP) of the nucleobases have been determined by means of photoelectron spectroscopy and photoionization mass spectrometry [32]. Values for the first vertical and adiabatic ionization potentials are summarized

Table 1. Experimental and calculated ionization potentials (IP) and electron affinities (EA) of the nucleobases^a.

Base	IP _{ad} ^b	IP _{vert} ^c	IP _{calcd} ^d	EA _{ad} ^e	EA _{vert} ^f
Guanine, G	7.77	8.24	8.04	−1.23	−0.7
Adenine, A	8.26	8.44	8.48	−0.74	−0.3
Cytosine, C	8.68	8.94	9.00	−0.40	0.2
Thymine, T	8.87	9.14	9.45	−0.32	0.3
Uracil, U				−0.19	0.4

^aData from Ref. [33]. Values in electron volts (1 eV = 23.045 kcal mol^{−1}). See Figure 1(b) for base structures.

^bExperimental adiabatic ionization potential.

^cExperimental vertical ionization potential.

^dCalculated vertical ionization potential.

^eCalculated adiabatic electron affinity (EA).

^fCalculated vertical electron affinity.

in Table 1. The order of both vertical and adiabatic IP values is $G < A < C < T$. Values of the Koopmans' IP (HOMO energy) obtained by Sevilla and coworkers [33] from *ab initio* calculations at the 3-21G level are in good agreement with the measured vertical IPs [32]. The vertical IPs are larger than the adiabatic values by an amount equal to the cation radical reorganization energy. The large difference in vertical and adiabatic IP values for G are attributed to more extensive geometric relaxation than is the case for the other nucleobases [34].

The effect of solvation on the IPs of nucleotides has been investigated by LeBreton and coworkers using a combination of photoelectron spectroscopy and computational methods. They conclude that the first and second ionization potentials of the nucleotides deoxycytidine 5'-phosphate (CMP) and deoxythymidine 5'-phosphate (TMP) arise from ionization of the negatively charged phosphate group and nucleobase, respectively, both in the gas phase and in solution. The difference in the calculated first and second ionization potentials is smaller for the hydrated versus gas phase nucleosides as a consequence of the larger solvation energy for the zwitterion formed upon ionization of the nucleobase versus the neutral radical formed upon ionization of the phosphate. The calculated adiabatic ionization potentials for the hydrated nucleobases CMP and TMP are 5.8 and 6.0 eV, respectively, considerably lower than the gas phase nucleobase ionization potentials (Table 1).

The electron affinities (EA) of the nucleobases have not been determined experimentally. Calculated values for the vertical and adiabatic EA obtained by scaling experimental and calculated values for other aromatic molecules are summarized in Table 1 [33a]. The vertical values follow the order $U > T > C > A > G$, with U having the largest (most positive) EA. The calculated adiabatic EA for C is less positive than the values for T or U. Chen and Chen [36] have asserted that the electron affinities of the purines are larger than those of the pyrimidines. However, this claim appears to be based upon questionable reduction potential measurements (see p. 114). The nucleobase anion radicals are estimated to be stabilized by c. 3 eV in aqueous solution.

Table 2. Calculated ionization potentials (IP) of single and stacked bases^a.

Base	IP (eV)	Bases	IP (eV)
Guanine, G	7.75	5'-GG	7.28
Adenine, A	8.24	5'-GA	7.51
Cytosine, C	8.87	5'-GC	7.68
Thymine, T	9.14	5'-GT	7.69
8-Oxoguanine (OG) ^b	7.54	5'-G _o G	7.06

^a Ionization potentials estimated from Koopmans' theorem from Ref. [38a] except as noted. See Figure 1(b) for base structures.

^b Data for OG from Ref. [39].

Base pairing of the nucleobases in duplex DNA can affect their calculated ionization potentials and electron affinities. Colson et al. [33b] reported that base pairing lowers the IP of guanine, but has little effect on the ionization of adenine in the A:T base pair. The effects of base pairing on ionization potentials has been investigated by Hunter and Clark [34] using *ab initio* and density functional calculations. The isodesmic relations in Eqs. 1 and 2 show that A⁺⁺ and G⁺⁺ are stabilized by 10.2 and 17.4 kcal mol⁻¹, respectively, upon base pairing.

Thus the difference in G versus A ionization potentials is larger for the base pair than for the individual base. The extra stabilization of the G:C⁺⁺ base pair is attributed to the strong hydrogen-bonding interaction in the central hydrogen bond of the G:C base pair. Base pairing is also reported to affect the calculated nucleobase EA, resulting in C having a higher (more positive) EA than T [33c].

The π -stacking of nucleobases in single-strand and duplex DNA also lowers their ionization potentials. Kim et al. [37] have recently reported that the experimental ionization potentials of the dinucleotide 5'pGpA is 2.0 eV lower than that of 5'dGMP. Calculations by Sugaiyama and Saito [38] indicate that the IP of G is lower when π -stacked with any of the four nucleobases, but that the effect is largest for adjacent guanines, a GG step (Table 2). Similar computational results have been obtained by Kim et al. [37] and Prat et al. [39]. This trend follows directly from simple perturbation theory, the largest splitting between interacting orbitals being expected when they have the same energy. The formation of stable dimer cation radicals is also observed for simple aromatics such as benzene in the gas phase [38]. An even larger stabilization energy is calculated for the cation radical formed from three versus two adjacent guanines [37, 38]. Schuster and colleagues [41] have suggested that cation radicals or electron holes in duplex DNA are delocalized over several adjacent stacked bases, a situation analogous to that of polarons in single crystals. Formation of dimer cation radicals or more highly delocalized polarons

should be accompanied by a decrease in the π -stacking distance as a consequence of decreased electron–electron repulsion between the stacked aromatic molecules.

The nucleobase analogue 7,8-dihydro-8-oxoguanine (OG; Figure 1b) is of particular interest as a likely intermediate in the oxidation of guanine [6, 7]. Calculations by Prat et al. [39] indicate that the IP of OG is c. 0.4 eV lower than that of G. Stacking of OG with guanine (either 3' or 5') results in a further decrease in the IP of OG.

Unlike the cation radicals of aromatic molecules, the anion radicals do not form stable dimer anion radicals, presumably due to an increase in electron–electron repulsion [42]. To our knowledge, there is no experimental or computational evidence for stabilization of nucleobase anion radicals upon π -stacking in duplex DNA.

Electrochemical oxidation and reduction

Solution-phase oxidation and reduction potentials of the nucleobases, nucleosides, and nucleotides have been determined using both electrochemical and radical ion equilibration measurements [42–47]. Table 3 summarizes the redox potentials of the nucleosides in the polar aprotic solvent acetonitrile determined by Seidel et al. [43] by means of cyclic voltammetry and the redox potentials in aqueous solution determined by Steenken and coworkers [42] by means of pulse radiolysis equilibrium analysis using time-resolved spectrophotometric detection. Also reported by Enescu and Linqvist [44] are the standard oxidation potentials of the nucleotides in water. The reduction potential of guanine is reported by Seidel et al. [43] to be too large to be measured in dimethylformamide (DMF) solution. A report that guanine was more easily reduced than the other nucleobases [36] is inconsistent with more recent data. Nucleobase analogues (Figure 1b) with altered redox potentials have been

Table 3. Nucleoside oxidation and reduction potentials in aprotic solvents and water^a.

widely used in studies of DNA electron transfer. Electrochemical potentials for several of these analogues are included in Table 3.

The nucleoside redox potentials measured in acetonitrile solution (Table 3) approximately parallel the gas phase adiabatic IP and calculated adiabatic EA of the nucleobases (Table 1). Namely, guanosine is more readily oxidized than adenosine by c. 0.4 eV, and thymidine is more readily reduced than cytidine by c. 0.1 eV. The difference between the guanosine and adenosine oxidation potentials in water reported by Steenken et al. [42a,b] is much smaller than the value reported by Enescu and Linqvist [44] ($\Delta E_{\text{ox}} = 0.13$ and 0.40, respectively; Table 3). A larger difference appears to be more consistent with observations of selective oxidation of guanine in DNA [6, 7]. The absolute value of the redox potentials determined in aqueous solution are much smaller than those measured in nonaqueous solution (Table 3). The large differences in experimental oxidation potentials in acetonitrile versus water are attributed by Seidel et al. [43] to a combination of the increased solvation energy in water (c. 0.1 eV) and coupled electron transfer and proton transfer (c. 0.3 eV). Oxidation and reduction of the nucleosides results in a large increase in their acidities and basicities, respectively, leading to significant differences in their aqueous potentials measure under acidic, neutral, and basic conditions [42]. Seidel et al. [43] note that there is no satisfactory explanation for the large discrepancy between the electrochemical reduction potentials determined in nonaqueous solution and the values obtained by pulse radiolysis in aqueous solution.

Both base pairing and π -stacking are expected to affect the magnitude and possibly the relative order of the nucleoside redox potentials. Steenken et al. [42a] have used thermodynamic cycles to predict the equilibrium constant for proton transfer in oxidized or reduced base pairs. The calculated equilibrium constant for proton transfer in the $\text{C}^{\cdot-}:\text{G}$ base pair is large ($K \geq 10^3$) compared to that for the $\text{A}:\text{T}^{\cdot-}$ base pair ($K \leq 10^{-7}$). This difference could account for the localization of electrons on G:C base pairs, in spite of the larger EA and nonaqueous reduction potential of T versus C. The calculated equilibrium constant for proton transfer in the $\text{C}:\text{G}^{+\cdot}$ base pair ($K \sim 2.5$) is also much larger than for the $\text{A}^{+\cdot}:\text{T}$ base pair ($K \geq 10^{-6}$). This would reinforce the preference of an electron hole for a G:C versus A:T base pair. Steenken [18a] has suggested that rapid proton transfer in oxidized or reduced base pairs would effectively trap the electron or hole, and thus preclude long-range electron transfer in DNA. Recent experimental evidence (Section 5.4) indicates that this need not be the case.

There have been several reports of the complex electrochemical behavior of single-strand and duplex DNA absorbed on electrode surfaces [48]. However, there have been no reports to date of the measurement of nucleotide oxidation or reduction potentials in duplex DNA. Johnston and coworkers [49] have used electrochemical methods to study the dynamics of the selective oxidation of guanine in single-strand and duplex DNA by $\text{Ru}(\text{bpy})_3^{3+}$ which is generated by oxidation of $\text{Ru}(\text{bpy})_3^{2+}$ (Eqs. 3 and 4).

The reduction potential of $\text{Ru}(\text{bpy})_3^{3+}$ is sufficiently large to oxidize guanine, but not the other nucleobases. When the guanine density is low, its oxidation requires binding of $\text{Ru}(\text{bpy})_3^{3+}$ in a 2.5–5-bp region containing a guanine [49e]. DNA sites containing GG or GGG steps are more readily oxidized than those containing a single guanine. $\text{Os}(\text{bpy})_3^{3+}$ is found to oxidize OG, but not guanine [49e]. The rate constants for guanine and OG oxidation by $\text{Ru}(\text{bpy})_3^{3+}$ and $\text{Os}(\text{bpy})_3^{3+}$, respectively, are substantially slower for duplex versus single-strand DNA, but increase with the introduction of base mismatches. The dependence of rate on structure is attributed to distance dependence of the electron transfer process, with closer approach of the reactants being possible for single-strand versus duplex DNA and for mismatched versus base-paired duplexes. Alternatively, the higher effective oxidation potential of guanine in duplex versus single-strand DNA or mismatched duplexes may result from a difference in effective solvent polarity (Section 5.2).

5.1.3 Direct Ionization of DNA

Radical anion formation via radiolysis

Exposure of living cells to ionizing radiation can have lethal consequences which result from RNA and DNA single- and double-strand breaks [9]. Strand breaks result from a combination of free radical and electron transfer processes, the latter being known to result from the formation of nucleobase anion and cation radicals. Thus, the formation and migration of electrons and holes has been a topic of active investigation by radiation biologists and chemists for over four decades [50, 51]. A comprehensive review of these investigations is beyond the scope of this chapter, and thus only selected information is presented.

Radiolysis of aqueous solution results predominantly in the ionization of water to produce a hydrated electron, e_{aq}^- , and H_2O^+ [9]. The former species can be captured by any of the four DNA nucleotides, leading to the formation of their anion radicals [52]. The latter species transfers a proton to water, resulting in the formation of H_3O^+ and the hydroxyl radical, HO^\bullet . Abstraction of hydrogen atoms from DNA by HO^\bullet accounts for the majority of the strand cleavage which occurs upon radiolysis of DNA in aqueous solution [9]. Free radical reactions can be suppressed by the addition of radical scavengers or by irradiation in frozen glasses in which HO^\bullet radical migration is inhibited. Radiation of DNA in water can also result in its direct ionization, leading to the formation of nucleobase cation radicals and either anion radicals or solvated electrons.

The identity of the radical ions formed upon steady-state radiation of DNA in low-temperature glasses has been established by means of electron paramagnetic resonance (EPR) spectroscopy [53]. EPR analysis indicates that electrons and holes are localized on a single nucleobase rather than being delocalized over several stacked bases at low temperatures. Radical ion formation is presumed to occur randomly at all four nucleosides. However, EPR studies establish that the electron holes are localized predominately on guanine, which has the lowest gas phase ionization potential and solution oxidation potential (Tables 1 and 3). Yan et al. [54]

report that hole transfer from adenine to guanine in duplex DNA is nearly complete within several minutes at 100 K. Electrons can be localized on either cytosine or thymine, the two nucleobases with the highest EA and lowest solution reduction potentials. There has been some controversy over which anion radical is favored, the results appearing to depend upon experimental conditions. Yan et al. [54] report that both $T^{\cdot-}$ and $C^{\cdot-}$ are formed initially, but that $C^{\cdot-}$ is converted to $T^{\cdot-}$, which undergoes protonation upon annealing. Replacement of thymine by bromodeoxyuridine (BrU; Figure 1b), an isostere with lower reduction potential, results in trapping of electrons on BrU [55–57].

The reaction of hydrated electrons formed by radiolysis with peroxydisulfate yields the sulfate radical anion $SO_4^{\cdot-}$ which is a strong chemical oxidant ($E_{ox} = 2.4$ V/NHE) [50, 58]. The oxidation of both purine and pyrimidine nucleotides by $SO_4^{\cdot-}$ occurs with rate constants near the diffusion-controlled limit ($2.1\text{--}4.1 \times 10^9$ M⁻¹ s⁻¹). Candeias and Steenken [58a] employed absorption spectroscopy to investigate acid–base properties of the guanosine cation radical formed by this technique. The cation radical has a pK_a of 3.9, and is rapidly deprotonated at neutral pH to yield the neutral $G(-H)^{\cdot}$. Both $G^{+\cdot}$ and $G(-H)^{\cdot}$ have broad featureless absorption spectra with extinction coefficients <2000 at wavelengths longer than 350 nm. This has hampered the use of transient absorption spectra to study their formation and decay. Candeias and Steenken [58b] have also studied the oxidation of di(deoxy)nucleoside phosphates which contain guanine and one of the other three nucleobases by $SO_4^{\cdot-}$, and observe only the formation of $G^{+\cdot}$ under acidic conditions and $G(-H)^{\cdot}$ under neutral conditions.

The observation of electron and hole localization on the bases of highest EA and lowest IP, respectively, indicates that both electrons and holes can migrate via the stacked bases in duplex DNA, both in solution and in low-temperature glasses [53]. Using a statistical model, Yan et al. [54] concluded that the distribution of DNA radical ions observed at 77 K could be explained by the migration of cold (thermalized) holes and electrons over as few as two or three bp.

The distance over which electrons can migrate in aqueous solutions and glasses containing DNA has been investigated using added electron scavengers. Reduction of the nucleobase analogue BrU (Figure 1b), an isostere of thymine, results in loss of bromide ion [59]. Fielden et al. [55] employed fluorescence-detected pulse radiolysis to investigate the effect of increasing the BrU content upon the luminescence from dried fibers of native DNA from murine lymphoma cells. Assuming that luminescence results from radical ion pair annihilation, their results indicate that the electrons and holes can migrate over as many as 100 bp at 93 K. Recently, Razskazovskii et al. [57] used EPR spectroscopy to investigate the temperature dependence of electron migration in γ -irradiated samples of randomly brominated DNA, and concluded that electron migration can occur via an activationless process over distances of c. 11 bp at 77 K. At higher temperatures a second, activated migration process was observed and attributed to a hopping mechanism. Beach et al. [56] employed DNA from *E. coli* which was grown on cultures with variable BrU-content to study electron migration both in solution and in cells at room temperature; they concluded that electron migration occurred over 6–10 bp in solution, but only 5–6 bp in *E. coli*.

Figure 6. Intercalating dyes used in studies of charge migration in DNA.

The use of cationic intercalating dyes (Figure 6) as electron scavengers has been investigated by several groups [60–64]. Whillans [60] used pulse radiolysis with transient absorption detection to study trapping of electrons by the dyes proflavine and ethidium bromide. An upper limit of 5 bp was estimated for electron migration at room temperature in aqueous solution, and no evidence was found for free electron migration. Cullis and coworkers [61] used anthraquinone derivatives such as amantrene as electron-scavenging intercalators in their study of electron migration in DNA at 77 K in an aqueous glass. They concluded that the mean distance traveled by the ejected electrons prior to capture was c. 31 bp. O’Neil and coworkers [62a,b] have investigated electron migration to the intercalated dye misonidazole in solid freeze-dried DNA. Their initial conclusion was that mean distance of electron migration is 25 bp [62a]; however, re-analysis of their data provided shorter distances or 17 ± 2 [62b] and 5 to 10 bp [63].

Anderson and Wright [64] have recently investigated electron migration from reduced cytosine bases in DNA to several nitroacridine and nitroquinoline intercalators (e.g., 4-nitro-10-aminoacridine; Figure 6) at room temperature in aqueous solution by means of pulse radiolysis. The time scale for their measurements is 10^{-6} to 10^{-3} s, and is limited by the time required for capture of e_{aq}^- by DNA (c. 5 μ s) and by the decay time of C^{--} in the absence of intercalators (c. 230 μ s). Electron migration was found to be an activated process, the rate of which is dependent upon both the average separation between the C^{--} donor and the intercalator and the driving force for electron transfer. The average migration distances for several different acceptors were in the range 3–7 bp, somewhat shorter than those obtained in previous experiments. The observation of longer electron migration distances at 77 K versus room temperature in studies with both intercalators and BrU as electron scavengers is consistent with the occurrence at room temperature of an activated trapping process such as proton transfer, which competes with electron migration. The results of Anderson and Wright [64] suggest that the rates of proton

transfer processes occur on the μs time scale, rather than the much faster rates recently suggested by Steenken [18a].

The use of pulse radiolysis to study charge migration in DNA has clearly established that electron migration from base radical anions to electron scavengers can occur over distances of c. 3–10 bp at room temperature, and longer distances at low temperatures. These processes are initiated by random scavenging of the hydrated electrons by all four DNA nucleobases, and terminated by electron transfer to randomly positioned BrU or intercalated scavengers. Thus only average electron migration distances can be estimated. To date, no information is available from pulse radiolysis studies concerning the migration of cation radicals (hole migration). Furthermore, the μs time scale of initiation is too slow to permit direct measurement of the dynamics of rapid charge transfer processes.

Radical cation formation via photoionization

Low-intensity 254 nm ultraviolet irradiation of DNA results in pyrimidine photohydration and photodimerization [8]. Photoionization of nucleobases can be effected by the absorption of a single 193-nm photon or two photons of lower energy (typically 248 or 266 nm) [65]. The availability of ArF excimer lasers has facilitated the investigation of 193-nm single photon excitation. Quantum yields for cation radical formation from nucleobases and single-strand and duplex DNA are typically 0.02–0.05, and are not highly nucleobase-dependent [66]. Quantum yields for two-photon 246-nm excitation are power-dependent, and are typically much lower than for 193-nm single-photon excitation. The nucleobases absorb most of the incident ultraviolet light, and thus are photoionized in preference to the phosphate groups.

The migration of electron holes formed by means of photoionization has been investigated in a di(deoxy)nucleoside phosphate, single-strand, and double-strand DNA. Candeias and Steenken [58b] found that in the case of adenylylguanonsine hole transfer from $A^{+\bullet}$ to guanine is complete within 50 ns, the time resolution of their 193-nm laser flash photolysis apparatus. Similarly, the electron holes in ss DNA are localized on guanine within 50 ns of laser excitation [66b]. O'Neill co-workers [67] have investigated hole migration in RNA and several ss oligo(deoxy)nucleotides. They find that in RNA hole migration to guanine is complete within the μs time resolution of their laser flash photolysis experiment. Hole transfer from $A^{+\bullet}$ or $C^{+\bullet}$ to guanine in the oligonucleotides is >80 % complete on this time scale, from which they concluded that the distance of hole migration in single-strand oligonucleotides is limited to two or three bases.

The photoionization of ds DNA has been investigated using both single-photon 193-nm and two-photon 248- or 266-nm excitation [65–69]. As is the case for ss DNA and RNA, transient absorption spectra recorded on a μs time scale indicate that the holes are located predominantly on guanine. Photoionization results in both single- and double-strand breaks in duplex DNA, with initial studies establishing that strand breaks occur preferentially at guanine [65]. Recently, Sies et al. [68] have reported that strand breaks occur preferentially at sites where there are two adjacent guanines (GG step) or, less often, where a guanine is adjacent to adenine. These results are indicative of hole migration from the locus of photo-

ionization to GG or GA sites which function as hole traps due to their low ionization potentials (Table 2). The selectivity of strand cleavage at GG sites is more pronounced for 193-nm versus 248-nm excitation. Angelov et al. [69] have studied the photoproducts formed upon 266-nm, two-photon excitation of DNA and find that both 8-oxo-7,8-dihydro-2'-dedoxyguanosine (OG; Figure 1b) and 7,8-dihydro-2'-dedoxyadenosine are formed. Thus, they conclude that adenine may serve as a secondary site for hole trapping in DNA.

Shafirovich et al. [70] have recently employed two-photon excitation of the nucleobase 2-aminopurine (AP; Figure 1b) to site-selectively generate cation radicals in both single-strand and duplex DNA. Since AP absorbs at wavelengths longer than 300 nm, the use of high-intensity 308-nm excitation results in photoionization of AP, but not the natural nucleobases. The efficiency of photoionization follows the order: free AP > ss > ds, with estimated quantum yields of 0.1 and 0.002 for ss and ds photoionization, respectively. These low quantum yields are attributed to rapid quenching of singlet AP by neighboring nucleobases, a process which is more efficient in ds versus ss DNA (Section 5.3.3, p. 151). Quenching shortens the AP singlet lifetime and decreases the probability of two-photon absorption. Using nanosecond transient absorption spectroscopy, electron transfer from GG steps to AP⁺⁺ could be detected in single-strand but not in duplex DNA. The efficiency of strand cleavage in both ss and ds DNA was found to decrease rapidly with increasing separation between the photoionized AP and the GG step.

Shafirovich et al. [71] have also investigated the migration of electrons photo-injected into DNA by two-photon excitation (335 nm) of pyrene derivatives covalently bound to ss and ds DNA. They find that in ds DNA the photoinjected electrons migrate to the acceptor methyl viologen (MV²⁺; Figure 6) which is bound to the DNA within the c. 7-ns time resolution of the laser apparatus. From the dependence of the MV⁺ yield upon the MV²⁺ concentration, and the assumption of a random distribution of the pyrene donor and MV²⁺ acceptor, they conclude that the photoinjected electrons have an average migration distance of 12 bp. No fast electron migration is observed in ss DNA, indicating the necessity of base stacking for electron transport and for binding of MV²⁺.

5.2 Collisional and Static Contact Electron Transfer in DNA

5.2.1 Energetics and Dynamics of Direct Electron Transfer Processes

Nucleobases can serve as either electron donors or electron acceptors in photo-induced electron transfer reactions with electronically excited acceptors (Ac) or donors (D), respectively. The free energy of photoinduced electron transfer reaction in which the nucleobase (N) serves as a donor or acceptor can be estimated using the Rehm–Weller equations (Eqs. 5 and 6), respectively,

$$\Delta G_{\text{et}} = E^0(\text{N}^{+\bullet}/\text{N}) - E^0(\text{Ac}/\text{Ac}^{-\bullet}) - E^*(\text{Ac}) + \Delta G^\circ(\varepsilon) \quad (5)$$

$$\Delta G_{\text{et}} = E^0(\text{D}^{+\bullet}/\text{D}) - E^0(\text{N}/\text{N}^{-\bullet}) - E^*(\text{D}) + \Delta G^\circ(\varepsilon) \quad (6)$$

where E^* is the singlet or triplet 0,0 energy of the excited state and $\Delta G^\circ(\epsilon)$ is a solvent-dependent correction term that is small (c. -0.1 V) in water and polar organic solvents [72]. The ion pair formed in the charge separation process can return to the ground state by means of return electron transfer (charge recombination). The free energy for this process is simply the sum of the redox potentials.

The oxidation and reduction potentials of the nucleosides in water or organic solvents (Table 3) can be employed to calculate the free energies of electron transfer processes involving a single nucleoside in the corresponding solvent. The potentials of the π -stacked nucleobases in ds DNA have not been measured, and thus calculation of the free energy of electron transfer processes involving ds DNA require assumption of the appropriate potentials. In view of the hydrophobic character of the π -stacked base array we have proposed that the values for polar organic solvents are more appropriate than those for water, particularly in the case of rapid electron transfer processes that are not coupled to proton transfer [73].

The rate constants for collisional (dynamic) quenching can be determined experimentally from the dependence of excited state lifetime or luminescence intensity using the Stern–Volmer equation (Eq. 7),

$$\tau^0/\tau = I^0/I = 1 + k_q\tau^0[Q] \quad (7)$$

where τ^0 and τ are the lifetimes and I^0 and I are the intensities in the absence and presence of the quencher Q [74]. The observed rate is dependent upon the diffusion controlled formation and dissociation of an encounter complex (k_{diff} and $k_{-\text{diff}}$) and the activation-controlled rate constant for electron transfer (k_{et}) (Eq. 8). According to basic Marcus theory, the free enthalpy of activation and rate constant for an outer-sphere electron transfer process can be described by Eqs. 9 and 10, respectively,

$$k_q = k_{\text{diff}}(1 + k_{\text{et}}/k_{-\text{diff}}) \quad (8)$$

$$\Delta G^\ddagger = \lambda/(1 + \Delta G/\lambda)^2/4 \quad (9)$$

$$k_{\text{et}} \sim \exp(-\Delta G^\ddagger/RT) \quad (10)$$

where ΔG is the free energy of reaction (Eq. 5 or 6) and λ is the reorganization energy. One quantum mechanical version of Eq. 10 is provided by the single-mode Marcus–Levich–Jortner equation (Eq. 11) [75],

$$k_{\text{et}} = \frac{2\pi}{\hbar} \cdot \frac{H_{\text{DA}}^2}{\sqrt{4\pi\lambda_s k_B T}} \cdot e^{-S_c} \sum_{n=0}^{\infty} \frac{S_c^n}{n!} \cdot e^{-(\Delta G + \lambda_s + n \cdot \hbar \cdot \langle \omega_c \rangle)^2 / 4\lambda_s k_B T} \quad (11)$$

$$S_c = \frac{\lambda_i}{\hbar \cdot \langle \omega_c \rangle}$$

where \hbar is Planck's constant, k_B is the Boltzmann constant, T is the temperature, H_{DA} is the electronic coupling matrix element, S_c is the dimensionless nuclear coupling constant, ΔG is the free energy change (Eq. 5 or 6), λ_i is the nuclear reorganization energy, λ_s is the solvent reorganization energy, and $\langle \omega_c \rangle$ is average

vibrational frequency. Application to photoinduced electron transfer requires the assumptions that the initial (excited) state is vibrationally relaxed, that $\hbar\langle\omega_c\rangle \gg k_B T$, and that the donor and acceptor exist in a single minimized geometry.

Both Eqs. 10 and 11 predict that k_{et} should first increase as ΔG becomes more exergonic (normal region), reach a maximum, and then become smaller when ΔG becomes highly exergonic (inverted region). Rate constants for collisional electron transfer quenching increase with increasing exergonicity in the normal region, as predicted by Marcus theory, and become diffusion controlled when $\Delta G \leq -10$ kcal mol⁻¹ [72]. The rate constants remain diffusion controlled even for highly exergonic electron transfer, rather than decreasing in inverted region. Under these conditions quenching may occur by formation of a charge transfer-stabilized exciplex rather than by outer-sphere electron transfer [76].

Investigations of bimolecular quenching of excited-state donors and acceptors by nucleosides, nucleotides, and oligonucleotides are frequently complicated by the formation of ground-state complexes. Equilibrium constants for ground-state complexation are typically larger in water than in organic solvents due to hydrophobic association. Coulombic attraction may also favor complexation between positively charged acceptors and negatively charged nucleotides or oligonucleotides. Exceptionally large association constants are observed for ds DNA with positively charged species than can bind to multiple nucleobase donor sites in the major or minor groove, or can be intercalated between adjacent π -stacked base pairs. In cases where static quenching is exergonic, the rate constant for electron transfer can be significantly larger than the rate constant for luminescence, resulting in essentially complete luminescence quenching. The rate constants for such ultrafast electron transfer processes can be measured by transient absorption spectroscopy.

Ground-state association of the donor and acceptor results in static quenching. Since no diffusion is required, the rate constant for static quenching is described by Eq. 12,

$$I^0/I = 1 + K_S[Q] \quad (12)$$

where K_S is the equilibrium constant for 1:1 complex formation [74]. The occurrence of bimolecular quenching by both static and dynamic mechanisms can complicate the interpretation of electron transfer quenching rate constants obtained from Stern–Volmer plots. In the case where the ground-state complex is non-fluorescent, the expression for lifetime quenching (Eq. 7) remains unchanged. However, the expression for intensity quenching is replaced by Eq. 13,

$$I^0/I = (1 + K_D[Q])(1 + K_S[Q]) \quad (13)$$

where K_D is the Stern–Volmer constant for dynamic quenching, $k_q\tau^0$ [74]. This form of the Stern–Volmer equation is second order in $[Q]$, resulting in upward curvature for plots of I^0/I versus $[Q]$. Thus, measurement of k_{et} from fluorescence data requires either lifetime measurements or graphical separation of K_D and K_S . Alternatively, transient absorption spectroscopy can be employed to determine either the decay time of the singlet state or the rise time of the radical ions.

Figure 7. Energy level diagram for photochemical charge separation and charge recombination for an excited state acceptor (Ac) and donor nucleobase (N).

Both dynamic and static electron transfer quenching of a neutral donor or acceptor by a nucleoside or nucleotide result in formation of a radical ion pair. The radical ion pair can decay by charge recombination to yield the ground state molecules (Figure 7), undergo chemical reactions, or diffuse apart [77]. The charge recombination of singlet radical ion pairs is a highly exergonic process. Thus, according to Eqs. 10 or 11 the rate constant for charge recombination should increase as the energy gap between the ion pair and ground state becomes smaller (inverted region). In the case of triplet radical ion pairs, charge recombination is spin forbidden, and thus a spin flip must occur prior to charge recombination. Intersystem crossing in strongly coupled triplet radical ion pairs is generally slow, and thus the triplet radical ion pair has a much higher probability of undergoing chemical reactions in competition with charge recombination than does the singlet radical ion pair.

5.2.2 Bimolecular Electron Transfer Processes of Nucleosides, Nucleotides, and Oligonucleotides

Neutral organic acceptors and donors

The fluorescence of the nucleobase analogues 2-aminopurine (AP) and 1,*N*⁶-ethanoadenine (EAD) is quenched by added nucleotides in aqueous solution [30]. The slopes of Stern–Volmer plots for quenching of fluorescence intensity follows the order $Z > G > I \sim A \sim C \sim T$; however, rate constants for static and dynamic electron transfer have not been reported. The singlet energy and ground- and excited-state reduction potentials are reported in Table 4, and are consistent with the oxidation of Z and G by an electron transfer mechanism in which the singlet state serves as an electron acceptor and the nucleotide as a ground-state donor (Eq. 5). Based on the results obtained with other singlet aromatic molecules (*vide infra*), it is

possible that the less efficient quenching observed for the pyrimidines involves oxidation of the singlet state (Eq. 6).

Pyrene has been widely employed as a fluorescent probe for biopolymers due to its strong and characteristic monomer and excimer fluorescence [78]. Lianos and Georghiou [79] investigated the ground- and excited-state interactions of pyrene with the nucleotides GMP, AMP, CMP, and TMP in aqueous buffer, and observed complex formation in both the ground and excited singlet states. The values of the ground-state association constants are larger for the purines than for the pyrimidines; however, this situation is reversed in the excited state. Quenching of singlet pyrene by the nucleotides occurs via both static and dynamic processes, except in the case of AMP for which little quenching is observed. The rate constants for dynamic quenching by GMP, CMP, and TMP are all near the rate of diffusion in water.

Geacintov et al. [80] reported similar results for quenching of the fluorescence of the benzo[a]pyrene tetraol metabolite BPT (Table 4) by nucleosides. An electron transfer mechanism for quenching was established using nanosecond transient absorption measurements. Quenching of singlet BPT by dG in the polar aprotic solvent dimethylsulfoxide (DMSO) results in formation of the BPT anion radical; however none of the other nucleosides is an effective quencher in DMSO. This result is consistent with an electron transfer mechanism in which BPT serves as the electron acceptor and dG as the electron donor (Eq. 5). Using the nucleoside oxidation potentials in acetonitrile solution from Table 3, photooxidation of dG is expected to be approximately isoergonic (Eq. 5), whereas oxidation of the other nucleosides is endergonic in polar aprotic solvents. Quenching of BPT by dG is also highly efficient in water, though the BPT anion radical is not observed, presumably due to rapid charge recombination. Quenching of singlet BPT by dT or dC in aqueous solution results in formation of the BPT cation radical. The observation of electron transfer quenching in water, but not in DMSO, is consistent with the much lower (less negative) nucleoside reduction potentials in aqueous solution (see Table 3).

The most detailed investigation to date of electron transfer quenching by nucleosides and nucleotides is that of Seidel et al. [43], who investigated the static and dynamic quenching of eight fluorescent coumarin derivatives in water. Depending on the redox properties of the singlet excited coumarin and nucleoside, the coumarin can function as either the electron donor or electron acceptor. For example, the coumarin C120 (Table 4) is reduced by guanosine and oxidized by thymidine or cytidine. The fluorescence of C120 is slightly enhanced upon complexation with adenosine. Similar results are observed for quenching by nucleotides. Correlations of the rate constants for dynamic quenching in water with the standard free energy for photoinduced electron transfer obtained using nonaqueous redox potentials are qualitatively similar in appearance to that observed by Rehm and Weller for aromatic donors and acceptors in organic solvents [72a]. However, the calculated values of ΔG_{et} underestimate the apparent values in aqueous solution by 0.5 to 0.9 eV! The solvation energy in water accounts for only a small part of this difference (c. 0.1 eV) and the remainder is attributed to a combination of proton-coupled electron transfer and hydrophobic interactions. No quenching of the coumarin singlets is observed in either hydroxylic (methanol, ethanol) or nonhydroxylic (aceto-

nitrile, dimethyl formamide (DMF)) solvents, in accord with the higher nucleoside oxidation potentials in nonaqueous solvent (see Table 3).

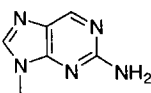

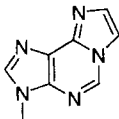

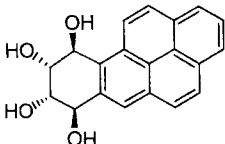

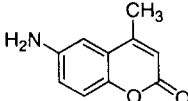

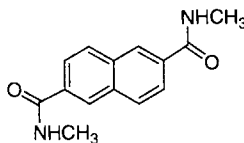

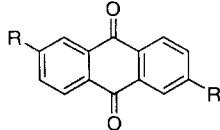

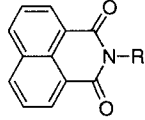

Lewis et al. [73] have reported the occurrence of static and dynamic quenching of the singlet acceptor 2,6-naphthalenedicarboxamide (NA; Table 4) by nucleosides in both aqueous and an organic solvent, DMF. Static quenching was observed for all four nucleosides with similar efficiencies in both water and DMF. The rate constants for dynamic quenching by the purines and pyrimidines are similar in water ($k_{\text{qd}} = 1.2\text{--}2.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$); however, the purines display larger rate constants than the pyrimidines for dynamic quenching in DMF. This result is consistent with exergonic quenching of singlet NA by all four nucleotides in water, but only by the purines in DMF.

Triplet acceptors have received less attention than their singlet counterparts. The longer lifetimes of triplet versus singlet acceptors provides a kinetic advantage in studies of dynamic quenching, but not in studies of static quenching. The triplet state of pyrene is not quenched by nucleosides in either aqueous or organic solvents [80]. The lower excitation energy of the pyrene triplet versus singlet (see Table 4) renders electron transfer quenching of the triplet endergonic. Anthraquinone derivatives have been used by Armitage and coworkers [81] in their studies of charge transport in DNA (Section 4.4). Due to their rapid intersystem crossing rate constants and high reduction potentials, anthraquinones are expected to be excellent triplet acceptors. The anthraquinone derivative AQC(2) (Table 4) forms a ground-state complex with GMP. Excitation of this complex results in the formation of the anthraquinone anion radical, which has been detected by transient absorption spectroscopy. The growth of $\text{AQC}^{\cdot -}$ is biphasic, the faster component occurring within 50 ps and the slower component extending to 5 ns. The $\text{AQC}^{\cdot -}$ formed upon reaction of the triplet with DNA decays slowly via spin-forbidden charge recombination in the absence of oxygen (c. 5 ms is required for complete decay). The decay of $\text{AQC}^{\cdot -}$ is more rapid in the presence of oxygen (10 μs in aerated solution), presumably due to electron transfer to oxygen.

Bernstein et al. [82] have recently investigated the dynamics of collisional quenching of triplet C_{60} by silyl derivatives of guanine and 8-oxoguanine in benzonitrile solution. The observed rates are $3.3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ and $1.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, respectively, in accord with an electron transfer mechanism in which the silylated nucleobase of lower oxidation potential (Table 3) is the better electron donor.

Saito et al. [83] have reported that bimolecular quenching of the triplet state of the naphthalene imide NIa (Table 4) by the oligonucleotide 5'TTGGTA results in the formation of the anion radical $\text{NIa}^{\cdot -}$. The triplet decay time of the triplet transient absorption is the same as the rise time of the anion radical, providing a bimolecular rate constant of $5.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. Rogers and Kelley [84] have recently studied the quenching of several triplet imide and diimide derivatives by the four nucleotides. Quenching of the naphthalene imide NIb and diimide derivatives (Table 4) is more rapid in the case of GMP than the other three nucleotides. Lower kinetic selectivity is displayed by a triplet benzophenone diimide, which is a more powerful triplet-state oxidant. Bimolecular quenching of the triplet naphthalene imides and diimides by calf-thymus DNA also results in formation of the acceptor anion radicals. However, no anion radical formation is observed when the naphthalene imide acceptors

are associated with DNA. Presumably electron transfer from DNA nucleobases to the associated imide singlets is more rapid than imide intersystem crossing, and singlet-state charge recombination is faster than the 0.1 μ s time scale of the transient absorption measurements.

Cationic organic acceptors

The photophysical and photochemical behavior of the phototoxic cationic acridinium and phenothiazinium dyes (Table 5) with nucleic acids have been widely investigated [85–87]. Both classes of dyes form ground-state complexes with nucleotides and oligonucleotides and are quenched by static and dynamic mechanisms. Ground-state equilibrium constants for *N*-methylacridinium (MA^+) are larger for GMP and AMP than for CMP or TMP; however, the dynamic quenching constants are diffusion controlled for all four nucleotides [85]. The short-lived fluorescence of methylene blue (MB^+) is quenched by the purines xanthosine (XMP; Table 3) and GMP but not by AMP (which slightly enhances the MB^+ fluorescence) or the pyrimidine nucleosides [87]. The fluorescence of thionine (TH^+) is quenched by AMP as well as GMP in accord with its larger singlet-state oxidation potential (Table 5) [86]. The singlet-state lifetimes of MB^+ and TH^+ are reduced from c. 400 ps in the absence of nucleotides to 6 ps and 1 ps, respectively, in the presence of GMP. Quenching of triplet MB^+ is observed with XMP but not GMP, in accord with the lower oxidation potential of the former.

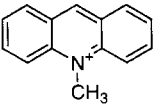

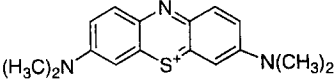

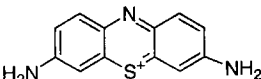

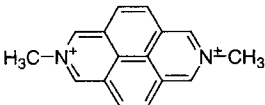

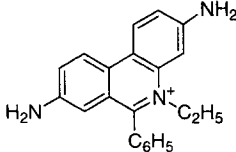

Enescu and Lindqvist [44] have investigated the deactivation pathways for the complexes of several purine nucleotides with MB^+ by means of picosecond transient absorption spectroscopy. They observe rapid biexponential decay of complexes of singlet MB^+ with GMP and XMP. The fast decay components ($\tau_1 < 10$ ps) were attributed to solvent relaxation and the slower decay components ($\tau_2 \sim 50$ ps for GMP and 10 ps for XMP) to charge transfer (Eq. 14),

where v and r are the vibrationally excited and relaxed states, respectively. Only slow decay attributed to charge transfer was observed for AMP (400 ps) and IMP (150 ps), in accord with their higher oxidation potentials (see Table 3). The absence of any intermediate detectable by transient spectroscopy was attributed to rapid charge recombination. In the case of the TH^+ -GMP system, >95 % recovery of ground-state bleaching occurs within 5 ps [86].

The dynamics of both static and dynamic quenching of the fluorescent singlet states of diazapyrenium salts by nucleotides has been investigated by Brun and Harriman using sub-nanosecond time-resolved transient absorption spectroscopy [88]. Observation of the reduced acceptor $\text{DAP}^{+\bullet}$ (Table 5) supports an electron transfer mechanism for fluorescence quenching. Diffusion-controlled rate constants were observed for quenching of DAP^{2+} by all four deoxynucleotides. Excitation of

^a Excited state energies in eV, redox potentials in V, versus NHE.

the ground-state complexes formed between DAP²⁺ and the nucleotides resulted in rate constants of $c. 5 \times 10^8 \text{ s}^{-1}$ for charge separation, much slower than normally observed for contact charge-transfer complexes in organic solvents [89]. Brun and Harriman [88] suggest that these slow rates may reflect a large D–A separation and unfavorable D–A geometry for electron transfer in the ground-state complex. Charge recombination of the geminate ion pairs is even slower than charge separation, in accord with the large change in free energy accompanying this process (Figure 7). Rate constants for charge separation increase as the calculated ΔG_{et} becomes more exergonic, reaching a maximum value when $\Delta G_{\text{et}} \approx 10 \text{ kcal mol}^{-1}$,

and rate constants for charge recombination decrease as this process becomes more exergonic, in accord with the predictions of Marcus theory (Eqs. 10 and 11).

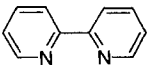

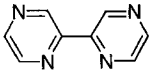

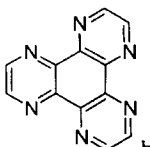

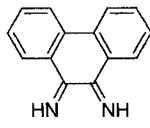

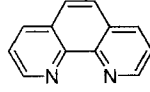

The dynamics of electron transfer from purine nucleotides to singlet excited ethidium cation (ET^+ ; Table 5) has been recently investigated by Barton and Zewail and colleagues [90]. They find that the fluorescence decay time of ground-state complex formed between ET^+ and G is somewhat longer than that of ET^+ in water (1.6 ns). However, the complex formed between ET^+ and the stronger donor Z (Table 3) has a fluorescence decay time of 70 ps. Analysis of the fluorescence anisotropy provided a longer decay time, leading to the proposal that the excited complex decays by a two-stage process similar to that proposed by Enescu and Lindqvist [45] (Eq. 14). As is the case for the MB^+ -nucleotide complexes, no transients assigned to the products of electron transfer are observed.

Transition metal complex acceptors

Luminescent polypyridyl Ru(II) complexes have been employed in numerous studies of DNA photooxidation [13, 14]. The dynamics of electron transfer quenching of the $^3\text{MLCT}$ states of Ru(II) complexes have been investigated by Krisch-De Mesmaeker and co-workers [14, 91]. The prototypical Ru(II) complex Ru(bpy)_3^{2+} is not a sufficiently strong oxidant or reductant to effect electron transfer from nucleotides or DNA. Ru(II) complexes with polyazaaromatic ligands (Table 6) are much stronger excited state oxidants than is Ru(bpy)_3^{2+} , and their luminescence is quenched by purine nucleotides in water [91]. A plot of $\log(k_{\text{et}})$ versus E^*_{red} for quenching of the $^3\text{MLCT}$ states by GMP and AMP has the appearance of a typical Rehm–Weller plot [72a]. Fitting of these data to the Marcus equation provides a value of $\Delta G^\ddagger = 7.5 \text{ kcal mol}^{-1}$ and values of 1.16 V and 1.56 V versus NHE for the oxidation potentials of GMP and AMP, respectively, in aqueous solution. The 0.4 V difference in GMP versus AMP potentials is larger than that reported by Steenken and Jovanovic [42b], but similar to that reported by Enescu and Lindqvist [44]. Laser flash photolysis of strongly oxidizing Ru(II) complexes with GMP yields transients which decay on the millisecond time scale and are assigned to the cage escaped Ru(I) complex and deprotonated GMP^+ .

Quenching of the excited states of several Rh(III) complexes possessing the ligands phi and phen (Table 6) by nucleosides and nucleotides has been investigated by Turro et al. [92]. The lowest excited states of the phi complexes are assigned to ligand-centered $\text{phi } n, \pi^*$ states which have decay times of c. 200–300 ns. Both static and dynamic quenching are observed for the negatively charged purine nucleotides, but only dynamic quenching for the neutral purine nucleosides. Rate constants for dynamic quenching by the both guanine and adenine bases, nucleosides, and nucleotides are all near the rate of diffusion in water. No quenching is observed for the pyrimidines. Laser flash photolysis of several complexes with GMP results in the formation of transients which are assigned to the reduced complex and oxidized GMP and which decay on the microsecond time scale. These may be cage-escaped products as in the above-mentioned study [91].

5.2.3 Electron Transfer Process Involving Covalently Attached Nearest-Neighbor Nucleobases

Electron transfer in mononucleoside and dinucleoside conjugates

The fluorescence decay of dinucleoside monophosphates containing the modified base ethanoadenine (EAD) (see Table 4) and the natural bases guanine and uracil have been investigated by Kubota et al. [31c]. The fluorescence quantum yields are lower for the conjugates than for the nucleotide of EAD (<0.1 versus 0.52). The observation of multiple exponential fluorescence decay was attributed to multiple conformations. A small component with a decay time similar to that of unmodified EAD was attributed to an extended conformation and two shorter components to loosely stacked folded conformations. While the mechanism of fluorescence quenching was not addressed, an electron transfer mechanism in which singlet EAD can serve as an electron acceptor (with guanine) or electron donor (with uracil) is

Figure 8. Structures of several arene-mononucleoside conjugates.

consistent with the results of Kelley and Barton for bimolecular quenching of EAD by nucleotides [30].

The behavior of purine nucleobases modified by covalent attachment of an aromatic hydrocarbon to the purine ring has been investigated by Geacintov and co-workers [80b, 93–95]. Extensive quenching of the fluorescence of the aminofluorene [93] and benzo[a]pyrene [94, 95] chromophores is observed in the conjugates AF-dG and BPT-dG (Figure 8). In the case of the BPT-dG conjugate, the formation and decay of BPT^{••} was observed by laser flash photolysis in DMF solution. The rate constants for charge separation and recombination are $9 \times 10^9 \text{ s}^{-1}$ and $2 \times 10^9 \text{ s}^{-1}$, respectively. These relatively slow rates for an intramolecular electron transfer process may reflect an unfavorable donor–acceptor geometry, as in the case of static quenching of DAP²⁺ by nucleotides studied by Brun and Harriman [88]. Formation of BPT^{••} is not detected in aqueous solution, presumably due to more rapid charge recombination [94]. Somewhat faster rate constants were observed for the *cis* versus *trans* stereoisomer of BPT, indicative of conformationally dependent quenching dynamics.

Relatively little fluorescence quenching is observed for the analogous conjugate of BPT with dA. However, when a second dG, dT, or dA nucleotide is attached to dA, fluorescence quenching is observed. Presumably, dT and dA serve as electron acceptors and singlet BPT as the electron donor. The extent of quenching is greater when the second nucleotide is attached to the 5' rather than the 3' position of the BPT-dA conjugate, providing further evidence for the dependence of quenching dynamics upon conformation.

The photophysics of several pyrene-dU conjugates have been investigated by Netzel and coworkers [96, 97]. Singlet pyrene serves as an electron donor, and uracil as an electron acceptor, in these conjugates. The conjugate P-dU (Figure 8) and an analogue with a carbonyl group separating the pyrene and uracil display charge-transfer fluorescence in organic solvents [96]. The observation of multiple exponential pyrene fluorescence decay was attributed to the presence of multiple ground-state conformers. The use of longer linkers containing amide groups also results in multiple exponential kinetics for quenching of singlet pyrene by dU [97].

The ground- and excited-state interactions between 7-alkoxycoumarin and nucleobases attached by a flexible trimethylene or pentamethylene linker ($\text{C}-(\text{CH}_2)_n\text{-dA}$, Figure 8) have been investigated by Wenska and Paszyc [98]. The equilibrium between folded and extended conformations favors the former in water and the latter in organic solvents. Dynamic quenching is observed in aqueous solution with rate constants that decrease in the order $\text{dA} > \text{dT} > \text{dU}$ ($k_q = 8.1 \times 10^8 \text{ s}^{-1}$ for dA connected via a trimethylene linker) in accord with an electron transfer mechanism in which the singlet coumarin serves as an electron acceptor and the nucleobase as electron donor. Dynamic quenching is more rapid for trimethylene versus pentamethylene linkers, as is generally observed for flexibly linked donor-acceptor systems. Dynamic quenching is also more rapid in aqueous versus organic solvent in accord with the lower base oxidation potentials in water (Table 3).

Seidel and coworkers [43, 99] have studied intramolecular quenching of the aminocoumarin C120 (Table 4) attached to mononucleotides by a flexible linker. They observe relatively slow quenching in water, with rates that decrease in the order $\text{dG} > \text{dT} > \text{dC} > \text{dA}$ ($k_q = 2.5 \times 10^8 \text{ s}^{-1}$ for dG and $0.2 \times 10^8 \text{ s}^{-1}$ for dA). This order is consistent with an electron transfer mechanism in which the coumarin serves as a weak acceptor in its reactions with purines, and as a weak donor in its reactions with pyrimidines. The observation of quenching in water but not in organic solvents is consistent with the observed effect of solvent upon nucleobase redox potentials (see Table 3). The behavior of C120 covalently attached to dinucleotides via a phosphorothiolate linkage adjacent to the 3'-terminus has also been investigated [99]. Variation of the 5' base with dA as the 3' base provides lifetime data for the dinucleotide conjugates indicative of quenching reactivity similar to that observed for the mononucleotide conjugates, $\text{dT} \sim \text{dG} > \text{dC} > \text{dA}$.

The intramolecular interaction of the 9-aminoacridine dye quinacrine with the nucleobases attached via a flexible polymethylene linker has been studied by Constant et al. [100]. The dye and nucleobase form π -stacked intramolecular complexes in water and, to a lesser extent, in organic solvents. Complex formation with adenine or thymine results in an increase in the acridine fluorescence intensity, presumably due to decreased solvation by water. In contrast, complexation with guanine results in quenching of the acridine fluorescence, presumably due to electron transfer.

Contact electron transfer in oligonucleotide conjugates

The fluorescence properties of oligonucleotides containing 2-aminopurine (AP; Table 4) have been investigated in several laboratories [29, 31]. Ward and Reich [29a] observed that the fluorescence intensity of the duplexes formed from the

alternating copolymers AP-U and AP-T is c. 0.1 to 1.5 % of that for the free AP monomer. Melting of the duplex results in an increase in fluorescence intensity. Law et al. [29b] also observed a c. 10-fold increase in fluorescence intensity upon melting of several 11-mers containing AP at the middle of one strand and each of the four nucleobases in the opposing position of the complementary strand. Nordlund et al. [29c] investigated the fluorescence of a 10-mer containing AP near the middle of one strand. The AP fluorescence decay was found to be multi-exponential. The longest decay time was assigned to an unstacked AP and three shorter decay times to AP with varying degrees of stacking with neighboring nucleobases. Hochstrassar et al. [29d] obtained similar results for ds DNA in which one strand has a 3'AP, and interpreted them in terms of multiple conformations ranging from fully stacked to unstacked. Kelley and Barton [30] also report low fluorescence quantum yields ($\Phi_f \leq 0.06$) and multiple exponential decays for duplexes containing AP, but do not address the possibility of quenching by neighboring nucleobases.

The photophysics of pyrene-oligonucleotide conjugates has been investigated in several laboratories [95, 101–103]. Quenching of singlet pyrene is more efficient when the conjugate BPT-dA (Figure 8) is incorporated into an 11-mer than in the simple mononucleotide conjugate [95]. Enhanced quenching was attributed to electron transfer involving neighboring nucleobases in either the ss or ds conjugate. When a P-dU conjugate (Figure 8) with a flexible linker is incorporated into an oligonucleotide, quenching by flanking nucleotides is observed to follow the order $C > T > G > A$ [101]. The greater reactivity for pyrimidines versus purines is consistent with an electron transfer mechanism in which singlet pyrene serves as the electron donor and the pyrimidine base as an electron acceptor. Duplex formation results in an increase in the pyrene singlet lifetime, presumably due to restricted access of the tethered pyrene to the acceptor nucleobases. Similar results were obtained for oligonucleotide conjugates in which a bispyrene with a flexible tether is attached to the 5'-end of the oligonucleotide [102]. The pyrene excimer fluorescence is more effectively quenched by neighboring T versus G in the ss conjugate. However, duplex formation eliminates this preference.

Electron transfer quenching in end-labeled pyrene-oligonucleotide conjugates with flexible linkers has been investigated by Zahavy and Fox [103]. The labeled strand is a purine 10-mer possessing one guanine and its complement a pyrimidine 10-mer. The presence of multiple ground-state conformations and the occurrence of quenching both by guanine and the pyrimidines complicates the kinetic analysis.

Nucleoside analogues in which an aromatic hydrocarbon replaces the natural base have been prepared by Ren et al. [25a]. Self-complementary oligonucleotides possessing a 5' terminal analogue (5'-dXCGCGCG, where X = pyrene, phenanthrene, or naphthalene deoxynucleosides) are thermodynamically more stable than the corresponding duplexes lacking the aromatic base. The thermal stability was taken as evidence for a duplex geometry in which the aromatic residue is π -stacked with the adjacent base pair. The fluorescence of both naphthalene and pyrene are reported to be strongly quenched in these duplexes. Fluorescence was observed for phenanthrene; however, neither quantum yields nor lifetimes have been reported for these duplexes.

The dynamics of quenching of the fluorescence of oligonucleotides labeled on the

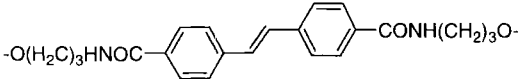

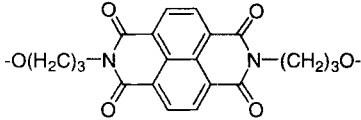

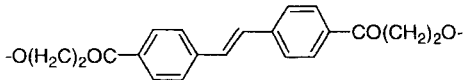

Figure 9. Three-state model for quenching of a rhodamine (F) end-labeled conjugate (G = guanine, N = other nucleobase) [105b]. Copyright 1998 National Academy of Sciences, U.S.A.

5' end by a 5-carboxytetramethylrhodamine dye (F; Figure 9) has been investigated by several research groups [104, 105]. Vámosi et al. [104] proposed a three-state model on the basis of their detailed analysis of steady-state fluorescence intensity and fluorescence decay data. According to this model, the tethered dye can exist in one of three ground-state conformations which do not interconvert on the time scale of fluorescence decay. One is a “dark state” in which the dye forms a ground-state complex with a quenching nucleobase, presumably guanine. The other two are both fluorescent but with different decay times in the range 0.5–1 ns and 2.5–3 ns. All three states are observed for both ss and ds DNA; however, the population of the dark state is higher for ds versus ss DNA. Subsequent investigations of rhodamine-oligonucleotide conjugates by single molecule fluorescence confirmed the presence of one dark and two fluorescent states. The three-state model proposed by Eggeling et al. [105b] is shown in Figure 9. According to this model, states A and B are the long-lived and short-lived fluorescent states whose decay times depend mainly on the local polarity, which is higher for rhodamine in water than when associated with the ss or ds oligonucleotide. The dark state C is assigned to ground-state complexation of rhodamine with guanine.

Oligonucleotide conjugates in which a Ru(II) complex is covalently attached to a modified pyrimidine nucleoside have been investigated by the groups of Netzel [106] and Kirsch-De Mesmaeker [107]. The former workers appended a modified $\text{Ru}(\text{bpy})_3^{2+}$ complex to a cytosine or thymine located near the middle of an 8-mer. The Ru(II) luminescence is not quenched in either the labeled ss or the duplex formed with its unlabeled complement, in accord with the low reduction potential of the $\text{Ru}(\text{bpy})_3^{2+}$ excited state (Table 6). The latter group has employed a photo-reactive $\text{Ru}(\text{TAP})_2\text{dip}^{2+}$ complex (TAP = 1,4,5,8-tetraazaphenanthrene and dip = 4,7-diphenyl-1,10-phenanthroline) tethered to a thymine located near the middle of a 17-mer. The relatively short tether forces the complex to remain inside the major groove of the duplex. The extent of luminescence quenching for several duplexes with different base sequences could be correlated with the proximity of the label to the nearest guanine.

Table 7. Structures, singlet energies (E^S), reduction or oxidation potentials (E_{rdn} or E_{ox}), and excited state reduction or oxidation potentials (E^S_{rdn} or E^S_{ox}) of DNA hairpin linkers.

Linker	Energetics
 <p>SA</p>	stilbenediamide [110] $E^S = 3.35$ $E_{\text{rdn}} = -1.67$ $E^S_{\text{rdn}} = 1.68$
 <p>DPA</p>	diphenylacetylenediamide [111] $E^S = 3.76$ $E_{\text{rdn}} = -1.74$ $E^S_{\text{rdn}} = 2.02$
 <p>NDI</p>	naphthalenediimide [112] $E^S = 3.24$ $E_{\text{rdn}} = -0.59$ $E^S_{\text{rdn}} = 2.65$
 <p>SE</p>	stilbenediether [26] $E^S = 3.45$ $E_{\text{ox}} = 1.16$ $E^S_{\text{ox}} = 2.29$

Contact electron transfer in bis(oligonucleotide) conjugates

The synthesis of bis(oligonucleotide) conjugates in which an arene-dicarboxamide (Table 7) serves as a linker connecting two oligonucleotides has been reported by Letsinger and co-workers [108]. The fluorescence intensities for conjugates possessing stilbene-4,4'-dicarboxamide linkers with mixed base sequence 5-mer arms are lower (Figure 10a) than that of the unmodified linker and are dependent upon the base sequence, conjugates in which a guanine is located adjacent to the stilbene being the least strongly fluorescent ($\Phi_f < 10^{-3}$). Conjugates such as the 10-mers A and B in Figure 10a display double or triple exponential decay, with one decay component longer and one or two components shorter than that of the linker with no attached nucleotides [109]. The decrease in fluorescence quantum yield is more pronounced than the decrease in the average lifetime.

These observations are consistent with the three-state model proposed by Vámosi et al. [104] for ss rhodamine-oligonucleotide conjugates. Similar results have been obtained for conjugates possessing naphthalenedicarboxamide linkers (NA; Table 4) [73]. In this case, dark states account for >90 % of the single-strand conjugates. Duplex formation between complementary bis(oligonucleotide) conjugates such as A and B (Figure 10a), both of which possess SA or NA linkers, results in the formation of duplexes which display strong excimer fluorescence from the stilbene or naphthalene excimer [73, 109].

Figure 10. Structures of (a) complementary bis(oligonucleotides) conjugates [109] and (b) hairpin-forming bis(oligonucleotides) conjugates [110].

Letsinger and Wu [108c] observed that conjugates containing stilbene-4,4'-dicarboxamide linkers and complementary arms form exceptionally stable hairpin structures (see Figure 5) [26]. Hairpins possessing polyA-polyT stems (e.g., T₆-A₆; Figure 10b) are strongly fluorescent; however, hairpins with polyG-polyC stems are essentially nonfluorescent. Subsequent investigations by Lewis and coworkers [110] established that a hairpin containing a single adjacent G:C base pair (1G:C; Figure 10b) undergoes charge separation to yield the stilbene anion radical and guanine cation radical with a rate constant of $1 \times 10^{12} \text{ s}^{-1}$. The radical ion pair decays to the ground state with a rate constant of $4.3 \times 10^{10} \text{ s}^{-1}$. The slower rate constant for charge recombination versus charge separation is consistent with the large energy gap for the latter process (Figure 7), which places it in the “inverted region” (Eq. 11). In contrast, the singlet stilbene in the hairpin T₆-A₆ does not undergo electron transfer quenching and has a singlet decay time of 2.0 ns, which is exceptionally long for a singlet stilbene. The oxidation of guanine but not adenine is consistent with the free energies of electron transfer calculated using Eq. 5 and the data in Tables 3 and 7 ($\Delta G_{\text{et}} = -0.3 \text{ eV}$ for G and $+0.2 \text{ eV}$ for A).

The observation of single exponential fluorescence decay for T₆-A₆ and charge separation and charge recombination rates for 1G:C indicates that these hairpins are conformationally homogeneous, unlike the other oligonucleotide conjugates and duplex-intercalator systems investigated to date. The high melting temperatures of the stilbene-linked hairpins suggests that their conformational homogeneity is a consequence of the thermodynamic stability of their B-form duplex structure (see Figure 5).

The free energy for photoinduced electron transfer in hairpin-forming bis(oligonucleotide) conjugates can be modified by changing either the nucleobase or the linker (Eqs. 5 or 6) [110–112]. Rate constants for charge separation and re-

Figure 11. Rate constants for charge separation (Δ) and charge recombination (O) in DNA hairpins with acceptor linkers (Table 7) and nearest-neighbor nucleobase donors [112].

combination in SA-linked hairpins are more rapid when guanine is replaced by 7-deazaguanine (Z), but are slower when the G:C base pair is replaced by an inosine-thymine (I:T) base pair, in accord with the reported oxidation potentials for Z and I (see Table 3) [112]. The 4,4'-diphenylacetylenedicarboxamide (DAP) [111] and naphthalenediimide (NDI) [112, 113] linkers are stronger singlet-state acceptors (Table 7) which can oxidize adenine as well as guanine. The stilbenediether linker (SE; Table 7) is a strong electron donor which can reduce either T or C [26].

A plot of the rate constants for charge separation and charge recombination obtained with SA, DAP, and NI acceptors and nucleobase donors versus exothermicity (ΔG_{et}) is shown in Figure 11. Rate constants for charge separation reach their optimum value of c. 10^{13} s^{-1} when $\Delta G_{et} \sim -0.5 \text{ eV}$. Rate constants for charge recombination decrease only slowly with increasing exothermicity. Both data sets can be fitted to Eq. 11 by making the simplifying assumption that the electronic coupling for charge separation and charge recombination is the same. This fit provides values of the solvent reorganization energy, $\lambda_s = 0.23 \text{ eV}$, the nuclear reorganization energy, $\lambda_i = 0.99 \text{ eV}$, and the electronic matrix coupling element, $H_{DA} = 347 \text{ cm}^{-1}$. The solvent reorganization energy is significantly smaller than values reported for aromatic contact radical ion pairs in polar solvents such as acetonitrile [77, 79], suggesting that the effective polarity of the duplex interior is similar to that of a moderately polar ether solvent [114]. The value of H_{DA} is con-

siderably smaller than that reported by Gould and Farid [77] for the contact radical ion pairs with cyanoanthracene acceptors and alkylbenzene donors (750 cm^{-1}). The smaller value may result from a rigid hairpin geometry which prevents optimal donor–acceptor overlap. A rigid geometry could also account for a value of λ_i which is lower than that observed by Hubig et al. [89] for charge recombination of olefin/TCNE charge transfer complexes. It is interesting to note that analysis of the data of Brun and Harriman [88] for charge separation and recombination of DAP^{2+} -nucleotide complexes provides a much smaller value of $H_{\text{DA}} = 1.2\text{ cm}^{-1}$, similar to the value reported by Gould and Farid [77] for a solvent-separated radical ion pair.

5.2.4 Electron Transfer Quenching of Intercalated Acceptors by Nearest-Neighbor Nucleobases

Intercalation of dyes into ds DNA can result in shifts in their fluorescence spectra and either increased or decreased fluorescence intensity [115]. Ethidium bromide (ET^+ ; Table 5) has been widely used as a fluorescent probe for DNA due to its marked increase in fluorescence quantum yield and lifetime upon intercalation ($\tau_s = 1.8\text{ ns}$ and 22.5 ns in water and DNA, respectively) [116]. The short lifetime of ET^+ in water is attributed to proton transfer quenching. The long lifetime of ET^+ when randomly intercalated in native DNA is consistent with its low singlet-state reduction potential ($E_{\text{rdn}}^{\text{S}} = 1.2\text{ V}$; Table 5) which renders quenching by guanine endergonic by c. 0.3 eV , using the oxidation potential of guanine in acetonitrile solution (see Table 3). Hall et al. [117] have observed that short-wavelength (310-nm) excitation of ET^+ covalently tethered to one end of a DNA duplex results in covalent bonding between ET^+ and an adjacent guanine. Since this reaction does not occur upon long-wavelength excitation of ET^+ , it is attributed to the reaction of an upper singlet state. The ultrafast dynamics of contact charge transfer processes make it possible for upper singlet state reactions to compete with internal conversion.

In contrast to the enhanced fluorescence of ET^+ upon intercalation, the fluorescence of many positively charged dyes is strongly quenched upon association with DNA [115]. Among these are the diazapyrenium dication (DAP^{2+}) and the methylene blue cation (MB^+). In view of the low singlet-state reduction potentials of these dyes (Table 5), photooxidation of neighboring purine nucleobases was suggested as the likely mechanism of quenching by Hélène and colleagues [118]. Brun and Harriman [88] have investigated the interaction of DAP^{2+} with ds DNA by means of time-resolved fluorescence and transient absorption spectroscopy. Their observation of multiple exponential fluorescence and transient decay was explained by the presence of dye molecules that are either fully and partially intercalated, loosely bound to the DNA exterior, or free in solution. Both charge separation and charge recombination for the fully intercalated dye were concluded to occur with rate constants $>10^{10}\text{ s}^{-1}$. These rates are much faster than those observed for the ground-state complex of DAP^{2+} with single nucleotides (see Section 5.2.2, p. 127), suggesting a more favorable geometry for electron transfer in the intercalated complexes. More efficient quenching and faster quenching rates were observed for

poly[dGdC] versus poly[dAdT], in accord with the lower oxidation potential of G versus A.

The dynamics of electron transfer quenching of intercalated MB^+ by neighboring base pairs have been investigated by Atherton and Harriman [119]. Intercalation of MB^+ is more favorable in poly[dGdC] than in poly[dAdT], surface binding competing with intercalation in the latter polymer. Intercalation results in a dramatic reduction in the MB^+ fluorescence quantum yield and decay time. Rate constants for the forward and return quenching processes in poly[dGdC] determined by transient absorption spectroscopy are $2.5 \times 10^{11} \text{ s}^{-1}$ and $3.3 \times 10^{10} \text{ s}^{-1}$, respectively. For MB^+ intercalated in poly[dAdT] the forward rate constant is $1.4 \times 10^{10} \text{ s}^{-1}$, and the return process was assumed to be even faster since the transient products of electron transfer were not observed. The quenching rates for surface-bound MB^+ are much slower. The authors suggested that the quenching process involved hydrogen atom transfer since the rate constants appeared to be too rapid for a non-adiabatic electron transfer process. However, recent studies have shown that even faster forward and return electron transfer processes can occur for π -stacked donor–acceptor contact complexes [110, 111].

Fast singlet-state contact electron transfer between intercalated acceptors and adjacent nucleobases can readily compete with intersystem crossing of the singlet acceptor. As previously described (Section 5.2.1), Kelly and colleagues [84a,b] observed that bimolecular electron transfer quenching of a naphthalene imide (NI; Table 4) by nucleotides occurs via a triplet-state mechanism. However, when intercalated in native DNA, quenching of the singlet state ($\tau_S = 2.4 \text{ ns}$) is more rapid than intersystem crossing [84b].

5.3 Single-Step Electron Transfer Process in Acceptor–DNA–Donor Systems

5.3.1 Background

As discussed in Section 5.2.1, the rate constant for a single-step superexchange electron transfer process between a donor and acceptor within a collision complex can be described by the Marcus–Levich–Jortner equation (Eq. 11). This equation also can be applied to bridge-mediated A–B–D systems under well-defined conditions in addition to those described in Section 5.2. First, the bridge states should lie well above the initial $\text{A}^*-\text{B}-\text{D}$ and final $\text{A}^--\text{B}-\text{D}^+$ states, as shown in Figure 12. Second, the A–B–D system must exist in a single conformation (or distribution of “kinetically equivalent” conformations) both prior to excitation and during the electron transfer process. Assuming that the energetics (ΔG_{et} and λ_i) for bridge-mediated electron transfer are independent of distance, the only term in Eq. 11 which is distance-dependent is H_{DA} , the electronic coupling matrix element. The distance dependence of H_{DA} is related to the donor acceptor distance (R) by Eq. 15 [75],

Figure 12. Energy level diagram for photochemical charge separation and charge recombination for an acceptor-bridge-donor (A-B-D) system.

$$H_{DA} = H_{DA}^0 \exp(-\beta(R - R_0/2)) \quad (15)$$

$$k_{et} = k_0 e^{-\beta R} \quad (16)$$

$$\beta = 2/R_0 \ln(\Delta E/t_{nm}) \quad (17)$$

where R_0 is a reference geometry and β is a characteristic of the specific donor-bridge-acceptor system. Combination of Eqs. 10 and 15 provides Eq. 16, the dependence of electron transfer rate upon β , where the pre-exponential factor k_0 is largely determined by the Franck-Condon factors for the electron transfer process. Finally, β is dependent upon ΔE , the energy gap between the initial and bridge states, and t_{nm} the electronic mixing matrix element between adjacent bridge sites. When $(\Delta E/t_{nm}) \gg 1$ this dependence can be approximated by Eq. 17.

Two types of A-B-D superexchange systems have been investigated experimentally, those in which an “unnatural” acceptor and donor are separated by a variable number of base pairs (Section 5.3.2) and those in which an “unnatural” acceptor is separated from the “natural” donor guanine (or a more readily oxidized base analogue or GG step) by a variable number of A:T base pairs (Section 5.3.3). The operation of a superexchange mechanism in either system requires that the excited acceptor not be quenched by the base pairs constituting the bridge. For the latter systems, this requires that the oxidation potential of adenine lies well above that of guanine. Based on the evidence presented in Section 5.1.2 (pp. 114–115), we conclude that this difference is ≈ 0.5 V. Both systems are also subject to complications arising from conformational disorder. Disorder in the A-B-D ground state (static disorder) may be reflected in multiple exponential decay of the A-B system in the absence of a donor. Dynamic disorder due to motion of the π -stacked base pairs forming the bridge could result in gating of the electron transfer process. Either type of disorder would result in an ensemble of values for k_{cs} . As is the case for contact electron transfer, the charge separation process is expected to lie in the normal region and charge recombination in the inverted region.

Equation 16 has been found to describe successfully the distance dependence of the electron transfer dynamics in a large number of systems in which there is a large energy difference between the oxidized or reduced states of the bridge and the initial and final donor–acceptor states [120]. In the case of proteins, the exponential dependence of electron transfer rate constant upon distance is observed for as much as a 10^{10} -fold decrease in rate constant [121]. Values of β for electron transfer in proteins and in D–B–A systems with hydrocarbon bridges typically fall in the range $0.9\text{--}1.6\text{ \AA}^{-1}$ [121, 122]. Electronic structure calculations by Beratan and colleagues [123] for stacks of benzene or naphthalene molecules separated by the 3.4 \AA π -stacking distance in DNA provide values of $\beta \sim 1.4\text{ \AA}^{-1}$. Similar values of β were calculated for several of the experimental systems discussed in the following sections. However, smaller values of β are observed for bridges with conjugated π -orbitals and an example of wire-like behavior in a D–B–A system with a *p*-phenylenevinylene bridge has recently been reported by Davis et al. [124].

Several alternatives to a superexchange mechanism for long-distance electron transfer in D–B–A systems have been advanced. Felts et al. [125] predicted on the basis of their solution to the Redfield equation for the density matrix of the full D–B–A system that an activated adiabatic mechanism which is only weakly distance-dependent might become significant under highly specific conditions. Davis et al. [126a] developed a similar model using a phenomenological treatment of the interaction of a quantum mechanical system with an external bath. This treatment has recently been extended to a full correlation–function treatment with both temperature and length dependence [126b]. Similar results have been reported by Mukamel and colleagues [127]. According to Felts et al. [125], the adiabatic pathway can result in rate constants faster than those for the distance-dependent superexchange mechanism under certain well-defined conditions. Among these is the requirement of thermal population of the bridge states which can occur only when the D–B gap is very small and the temperature is moderately high. Even under these conditions, the adiabatic mechanism may be slower than superexchange when the bridge contains only a small number of sites. Electron transport in DNA via a hole-hopping mechanism is discussed in Section 5.4 of this chapter.

The π -stacked bases of ds DNA might be expected to provide a better medium for bridge-mediated electron transfer than the sigma bonds of proteins or hydrocarbons. It has in fact been proposed by Turro and Barton [18d] that ultrafast photoinduced electron transfer processes involving intercalated donors and acceptors can occur with little or no distance dependence. According to this paradigm, duplex DNA can function as a “molecular wire” or “ π -way”.

5.3.2 Electron Transfer in Donor–DNA–Acceptor Systems

Nontethered intercalators

There have been numerous investigations of the fluorescence quenching of intercalated ethidium (ET^+ ; Table 5) by intercalated or groove bound quenchers [128–

134]. In the initial studies of Baguley and coworkers [128], ET^+ served as the electron acceptor and a series of 9-anilinoacridines as the electron donors. The efficiency of quenching was observed to be dependent upon the acridine oxidation potential, in accord with an electron transfer mechanism for quenching of the ET^+ fluorescence intensity and lifetime. Their fluorescence quantum yield and decay data has recently been re-analyzed by Tuite [11], who suggests that nearest neighbor binding of donor and acceptor results in total quenching and that quenching over longer distances results in a reduction in fluorescence intensity and lifetime. The efficiency of quenching was also found to depend upon the host nucleic acid, decreasing in the order poly(dAdT) > native DNA > poly(dGdC). This trend may reflect the dependence of electron transfer upon the average D–A separation, DNA structure, or the dynamics of the electron transfer quenching process.

Quenching of ET^+ fluorescence by diazpyrenium dichloride (DAP^{2+} ; Table 5) has been investigated by Brun and Harriman [129, 130]. Singlet ET^+ serves as the electron donor and DAP^{2+} as the electron acceptor in this system. Based on the data in Table 5, electron transfer should be exergonic by c. 0.26 eV. The decay of the ET^+ transient absorption and the formation and decay of the electron transfer products were directly observed by picosecond transient absorption spectroscopy. Time-resolved fluorescence studies reveal the presence of either three or four decay components, one of which has a decay time similar to that of unquenched intercalated ET^+ (21.1 ns). The several decay components both for charge separation and charge recombination are assigned to donor–acceptor separations of three, four, and five base pairs, in order of increasing decay time. It is asserted that no D–A pairs are separated by a smaller number of base pairs due to the mutual exclusion of intercalated molecules. However, it is unlikely that fluorescence would be observed for shorter D–A separations, as suggested by Tuite [11] in analyzing Baguley's results [128]. The slopes of plots of $\ln k_{\text{cs}}$ or k_{cr} versus R (Eq. 16) provide values of k_0 and β for electron transfer in calf-thymus DNA which are summarized in Table 8.

Table 8. Values of k_0 and β for superexchange DNA-mediated electron transfer^a.

System	k_0 (s^{-1})	β (\AA^{-1})
$\text{ET}^+/\text{DAP}^{2+}$ in calf-thymus DNA: charge separation	1.1×10^{13}	0.91
charge recombination [129]	1.3×10^{14}	1.49
$\text{ET}^+/\text{DAP}^{2+}$ in poly(dAdT)	2.5×10^{14}	1.0
$\text{ET}^+/\text{DAP}^{2+}$ in poly(dGdC) [130]	5.8×10^{13}	1.0
SA/G, (T:A) _n spacer, hairpin poly(dT) arm		
charge separation	7.8×10^{12}	0.66
charge recombination [110b]	1.6×10^{12}	0.90
SA/G, (T:A) _n spacer, in hairpin poly(dA) arm		
charge separation	3.2×10^{13}	0.71
charge recombination [110b]	6.2×10^{12}	0.94
Acridinium/G, (T:A) _n spacer [148b]	1.9×10^{12}	1.47
EA/G, (T:A) _n spacer [30]		1.0

^aData for systems in which kinetics based on kinetic spectroscopic data at several D–A distances is available.

Similar values of β are obtained when acridine orange is used in place of ethidium as the acceptor.

Harriman [130] has recently investigated the dynamics of electron transfer quenching of ET^+ fluorescence by DAP^{2+} in poly(dAdT) and poly(dGdC). Similar values of $\beta = 1.0 \text{ \AA}^{-1}$ are observed for both polymers; however, the rate constants for poly(dAdT) are c. four-fold faster at any fixed distance, in accord with the earlier observations of Baguley and coworkers [128]. The temperature dependence of the fluorescence decay data for quenching of ET^+ by DAP^{2+} has also been investigated by Harriman. Analysis of these data according to simple Marcus theory (Eqs. 9 and 10) provides a reorganization energy which approaches a value of $\lambda = 0.4 \text{ eV}$ as the D–A separation increases. Harriman points out that the small value of λ is indicative of a “rigid matrix that is not readily polarized”. The values of λ at shorter D–A separations (c. 0.48 eV) are somewhat larger than those that we observe for contact electron transfer in hairpin-forming bis(oligonucleotide) conjugates (0.23 eV ; Section 5.2.3). This difference may reflect the greater rigidity of hairpin versus normal duplex structures. Values for the electronic coupling matrix element H_{DA} decrease from c. 4 cm^{-1} at a D–A separation of 10 \AA to 0.1 at 17 \AA . These values are significantly smaller than our value for contact electron transfer (347 cm^{-1}) that is indicative of weak coupling across several base pairs.

Quenching of the luminescence of intercalated ET^+ by the intercalating complex $[\text{Rh}(\phi)_2\text{phen}]^{3+}$ (see Table 6 for ligand structures) was investigated by Kelley et al. [131]. Multiple exponential fluorescence decay is observed for ET^+ in the presence of the Rh(III) complex, as is the case in Hariman’s study of quenching by DAP^{2+} [130]. In fact, the 2 ns decay times reported by Barton are very similar to those assigned by Harriman to electron transfer between intercalated donor and acceptor separated by four and five base pairs in poly[dAdT]. Quenching of fluorescence intensity was also investigated and found to be more extensive than would have been expected on the basis of the fluorescence lifetime quenching. This result is consistent with static quenching at short donor–acceptor distances as suggested by Tuite [11].

The fluorescence of intercalated ET^+ is also quenched by methylviologen (Table 5; MV^{2+}), a surface-bound acceptor—a process which is exergonic by c. 0.08 V (Table 5). Quenching of the steady-state fluorescence of ET^+ by MV^{2+} was investigated by Fromherz and Rieger [132]. A large increase in the Stern–Volmer quenching constant upon addition of DNA was attributed to both the enhanced lifetime of intercalated versus free ethidium and the enhanced local concentration of MV^{2+} due to binding to DNA. Atherton and Beaumont [133] observed by means of transient absorption spectroscopy that both formation and decay of reduced MV^+ occurs within c. 1 ns. Harriman [130] has recently determined a rate constant of $6.3 \times 10^8 \text{ s}^{-1}$ for quenching of intercalated ethidium by nearest neighbor MV^{+2} under saturation conditions. From the temperature dependence of the rate constant, the activation energy for electron transfer ($\Delta G^\ddagger = 3.0 \text{ kcal mol}^{-1}$), reorganization energy ($\lambda = 0.66 \text{ eV}$), and electronic coupling matrix element ($H_{\text{DA}} = 18 \text{ cm}^{-1}$) were obtained. Similar values of λ were obtained for the quenching of several other intercalated dyes by MV^{2+} .

The quenching of intercalated ET^+ by metal ions has been investigated by Atherton and Beaumont [134a,b]. Both static quenching by metal ions associated

with the phosphate ions and diffusional quenching are proposed to occur. In the case of quenching by Cu^{2+} , most of the initially formed oxidized ethidium decays via geminate recombination with Cu^+ . The remaining oxidized ethidium undergoes multiexponential decay on a millisecond time scale. This decay was analyzed using a kinetic model that assumes reduction occurs via charge recombination with Cu^+ ions located at increasing fixed distances relative to the oxidized ethidium [134b]. This analysis provides a value of $\beta = 0.73 \text{ \AA}^{-1}$, though in view of the multiple assumptions made in arriving at this value, it should be viewed with circumspection.

The quenching of transition metal complexes bound to DNA has been extensively studied by Barton and coworkers [13]. In the initial studies of Barton, Turro and colleagues [135], marked enhancement of the efficiency of quenching of the electron donor $\text{Ru}(\text{phen})_3^{2+}$ by the acceptors $\text{Co}(\text{phen})_3^{3+}$ and $\text{Co}(\text{bpy})_3^{3+}$ (see Table 6 for ligand structures) was observed in the presence of DNA. Whereas it was initially suggested that DNA might be mediating efficient long-range electron transfer between intercalated complexes, later investigations showed that these complexes do not intercalate and that the primary effect of groove binding to DNA is to increase the local donor and acceptor concentrations and decrease their mobility [136], as proposed by Fromherz and Rieger [132] in their study of quenching of intercalated ET^+ by groove-bound MV^{2+} .

Metal complexes which possess one or more large planar aromatic ligand can intercalate strongly between the base pairs of DNA. The complex $[\text{Ru}(\text{phen})_2\text{dppz}]^{2+}$ has a binding constant of $>10^6$, and its luminescence intensity increases by $>10^3$ upon intercalation. This "light switch" behavior facilitates the distinction between electron transfer quenching of the free versus bound complex [137]. In 1994, Barton, Turro and coworkers [138] reported the remarkable enhancement of quenching of the luminescence intensity of this intercalated complex by an intercalated complex $\text{Rh}(\text{phi})_2\text{phen}^{3+}$ (Eq. 18) when compared to the nonintercalated complex $\text{Ru}(\text{N-H}_3)_6^{3+}$. Moreover, no quenching of the lifetime of $\text{Ru}(\text{phen})_2\text{dppz}^{2+}$ was observed on the nanosecond time scale. Based on the assumption that the donor and acceptor are bound randomly to DNA, the authors concluded that a quenching efficiency of $>80\%$ was obtained with an average D–A separation $\geq 35 \text{ \AA}$ (10 bp). No quenching of the $\text{Ru}(\text{phen})_2\text{dppz}^{2+}$ decay time was observed on a nanosecond time scale, from which it was concluded that the rate constant for charge separation is $>10^9 \text{ s}^{-1}$. A series of studies by these investigators using different metal complexes and oligonucleotides led to the conclusion that wire-like behavior required strong coupling between the donor and acceptor π ligands and the intervening aromatic base pairs [139]. Much less efficient electron transfer is observed when the quencher is groove-bound rather than intercalated [139d].

Subsequent investigation of this and related systems by Barton, Barbara and colleagues [140] using picosecond time-resolved fluorescence and transient absorp-

tion spectroscopy again failed to detect lifetime quenching, leading to a revised estimate $>3 \times 10^{10} \text{ s}^{-1}$ for the charge separation process. Charge recombination was also concluded to occur with rate constants $\sim 10^{10} \text{ s}^{-1}$ based on the absence of transient absorption by the products of charge separation. Two models for ultrafast charge separation and recombination were considered. A cooperative binding model with quenching over short D–A distances was rejected in favor of a random binding model with quenching over long distances. However, soon thereafter Olson et al. [141], independently of Barton, reported that the cooperative binding model was consistent with quantitative modeling of the available dynamic data. Kinetic modeling provided a value of $\beta = 1.0 \text{ \AA}^{-1}$ for the distance-dependent electron transfer in DNA. Concurrently, Lincoln et al. [142] reported that the intercalated donor and acceptor employed by Barton and Turro are bound cooperatively with only two base pairs separating nearest-neighbor donor–acceptor pairs. Barton has questioned the experimental evidence for cooperative binding, and presented evidence for anticooperativity in binding of $\text{Rh}(\text{phen})_2(\text{phen})^{3+}$ and $\text{Ru}(\text{phen})_2\text{dppz}^{2+}$ to a 10-mer duplex [139d, 144]. Further details of this controversy are provided in reviews by Barton [13], Barbara [15], and Tuite [11].

Tethered intercalators

The use of donors and acceptors that are covalently attached to an oligonucleotide reduces the uncertainty concerning location encountered with nontethered donors and acceptors. Barton and coworkers have used long, flexible tethers to attach chromophores to the 5' end of oligonucleotides [131, 144]. In 1993, they reported the remarkable observation that the intense fluorescence of the duplex formed between a 15-mer oligonucleotide with a tethered $[\text{Ru}(\text{phen})_2\text{dppz}]^{2+}$ chromophore and a nonlabeled complementary strand is completely quenched when the $\text{Ru}(\text{II})$ -labeled 15-mer is hybridized with a complementary strand possessing a 5'-tethered $[\text{Rh}(\text{phen})_2\text{phen}]^{3+}$ [144]. Photochemical studies of duplexes containing either the tethered $\text{Ru}(\text{II})$ or $\text{Rh}(\text{III})$ complex indicated that intercalation occurs with equal probability 1 or 2 bp from the 5' terminus [117]. On the assumption that this is also the case for the doubly labeled duplex, totally efficient luminescence quenching was concluded to result from ultrafast electron transfer over a distance of $\geq 41 \text{ \AA}$ (11 bp).

Kelley et al. [131] have also investigated the distance-dependent fluorescence quenching in duplexes containing a 5'-tethered ethidium on one strand and a 5'-tethered $[\text{Rh}(\text{phen})_2\text{bpy}]^{3+}$ on the complementary strand (Figure 13a). In the absence of $\text{Rh}(\text{III})$, a ET^+ -modified 10-mer duplex displays triple exponential decay with decay times of 7.6, 2.4, and 1.2 ns, presumably corresponding to three different duplex–intercalator geometries. In the presence of $\text{Rh}(\text{III})$ only modest changes in the decay times and preexponentials occur. When the length of the doubly tethered duplex was increased from 10 bp to 14 bp, the fraction of ET^+ fluorescence quenching by the $\text{Rh}(\text{III})$ complex decreased from 29 % to 8 %. The fluorescence intensity quenching was attributed to a long-range electron transfer process which is weakly distance-dependent. In support of this explanation, a single C:A base pair mismatch near the middle of a doubly labeled 10-mer reduces the extent of quenching from 21 % to 4 %.

tethered $\text{Rh}(\text{phi})_2\text{bpy}^{3+}$ acceptor on the complementary strand in extended and intercalated conformations. Reprinted with permission from ref. 131. Copyright 1997 American Chemical Society.

(b) Diagram of a duplex containing a 5'- $\text{Ru}(\text{bpy})_2\text{im}^{3+}$ acceptor on one strand and a 5'- $\text{Ru}(\text{NH}_3)_4\text{py}^{2+}$ donor on the complementary strand [146].

The observation of intensity but not lifetime quenching in the $\text{ET}^+-\text{Rh}(\text{III})$ doubly tethered system was attributed to “gated” electron transfer [131, 145]. According to this explanation, ultrafast long-distance electron transfer can occur only when the donor–acceptor and intervening base pairs are perfectly aligned. This would require that the excited states of the residual fluorescent duplexes adopt this optimal geometry no faster than the nanosecond time scale of the longest decay component—much longer than the picosecond time scales reported for many DNA relaxation processes (Section 5.1.2). The proposal of gated electron transfer also poses the question as to why this phenomenon was not observed for the $\text{Ru}(\text{II})$ - $\text{Rh}(\text{III})$ doubly tethered system? The observation of partial luminescence upon

mixing of two duplexes which possess a single tethered Ru(II) or Rh(III) complex [144] and self-quenching of the ET^+ -Rh system at concentrations $>20 \mu\text{M}$ [131] provide a possible explanation. End-to-end aggregation [19] of the Ru(II)-Rh(III) doubly tethered system would be favored by cooperative ligand interactions, and would result in a short distance between the Ru(II) in one duplex and the Rh(III) in the next.

DNA-mediated electron transfer between two nonintercalated tethered metal complexes has been investigated by Meade and Kayyem [146]. They prepared complementary 8-mer oligonucleotide conjugates in which two different Ru complexes are directly attached to the 2-amine of a 5' terminal aminosugar (Figure 13b). The reported distance between the two metal centers is 21 \AA ; however, the precise location of the metal complexes with respect to the duplex base pairs is not known. The rate constant for electron transfer between the acceptor Ru(III) and donor Ru(II) complexes was determined by the flash-quench technique to be $1.6 \times 10^6 \text{ s}^{-1}$. This single measurement is similar to that observed in proteins with similar D–A distances, and has been frequently cited as evidence against unusually facile electron transfer in DNA. However, in view of the importance attached to this study, it is unfortunate that additional experimental details have not been forthcoming.

Recently Aich et al. [147] have reported intriguing results for electron transfer in 20-mer and 54-mer duplex possessing a fluorescein electron donor at the 5' position of one strand and a rhodamine acceptor the 5' position of the complementary strand. No quenching of the fluorescein is observed in the normal B-form duplexes; however, upon addition of Zn^{2+} the duplex adopts a M-form geometry for which highly efficient quenching is observed in both the 20-mer and 54-mer (95 % and 76 % quenching, respectively). M-form DNA is proposed to adopt a double-helical structure similar to that of B-form DNA, with a metal ion replacing a proton in each base pair and a metal–metal distance of c. 4.0 \AA . Fluorescence decay measurements of the B-form and M-form 20-mer duplex show that the former has biexponential decay with components of 4.0 and 2.1 ns, and the latter triexponential decay dominated by a 10 ps component. The quenching process was concluded to occur via rapid, long-distance electron transfer. However, no definitive structural data is available for M-DNA and the radical ion products of electron transfer have not been detected. Thus, the claim of wire-like behavior must be viewed at this time with appropriate reservations.

5.3.3 DNA-Mediated Oxidation of Nucleobases

Stilbenedicarboxamide-linked DNA hairpins

As described in Section 5.2.3 (p. 136), the hairpin $\text{T}_6\text{-A}_6$ (Figure 10) which possesses a polyA-polyT stem and a stilbeneamide linker is strongly fluorescent. However, the adjacent G:C base pair in 1G:C results in totally efficient fluorescence quenching via an electron transfer mechanism [110]. Incorporation of a single G:C base pair at different positions relative to the stilbene linker permitted investigation

Figure 14. Distance-dependence of the rate constants for charge separation (open symbols) and charge recombination (filled symbols) for hairpin families in which guanine is either in the polyT arm (e.g., 3G:C, \circ , \bullet , solid lines) or in the polyA arm (e.g., 3C:G, Δ , \blacktriangle , dashed lines) [110b].

of the distance-dependent formation and decay of the stilbene anion radical by means of femtosecond time-resolved transient absorption spectroscopy. Rate constants for charge separation and charge recombination for two families of hairpins in which the guanine donor is located in either the poly[dT] or poly[dA] strand can be obtained from analysis of the transient decay data.

Plots of the log of the rate constants for charge separation and charge recombination versus the distance between the stilbene acceptor and guanine donor (calculated assuming a constant 3.4 Å π -stacking distance) are shown in Figure 14. The linear nature of these plots is consistent with a superexchange mechanism for bridge-mediated electron transfer (Section 5.3.1). According to Eq. 16, the slopes and intercepts from Figure 14 provide the values of β and k_0 summarized in Table 8. DNA-mediated electron transfer should be more favorable via a poly[dA] versus poly[dT] spacer due to the lower bridge energies for A versus T [120]. However, the experimentally determined values of β for both charge separation and charge recombination are only slightly larger when guanine is in the poly[dA] versus poly[dT] hairpin arm (Figure 14). This is a consequence of larger rate constants for short D–A separations ($n < 5$) for guanine in the poly[dA] arm but similar rates at long D–A separations ($n = 5$). Thus, the kinetic advantage for electron transfer via a polypurine versus polypyrimidine strand appears to be rather small, and to operate only over short distances.

The effects of donor oxidation potential upon the dynamics of charge separation and recombination has been determined for several donors (guanine, deazaguanine, oxoguanine, deazaguanine, and inosine; Table 3) separated from the stilbenedimethylcarboxamide linker by two T:A base pairs. Analysis of the kinetic data for charge separation and recombination according to Eq. 11 provides values of the solvent and internal reorganization energies, λ_s and λ_i , similar to those for nearest neighbor quenching (Figure 11). However, the electronic coupling matrix element $H_{DA} = 25 \text{ cm}^{-1}$, substantially smaller than the value of 347 cm^{-1} for nearest-neighbor quenching. The smaller value of H_{DA} is consistent with weak coupling of the donor and acceptor with the base pairs of the bridge, as observed by Harriman [130].

The dynamics of charge separation and recombination have also been determined for hairpins containing a GG step separated from the stilbene linker by two T:A base pairs [110b]. Cleavage of native and synthetic DNA by photonucleases occurs selectively at GG steps [6, 7] which have been proposed to function as hole traps as a consequence of their low oxidation potentials (see Table 2). The value of k_{cs} for a GG step is two to three times faster than that for an isolated guanine—a rate enhancement similar to that for the nucleobase Z. However, the value of k_{cr} is two to three times slower than that for an isolated guanine, whereas k_{cr} for Z is faster than that for guanine. Delocalization of the hole over the two guanines in the GG steps may be accompanied by contraction of the GG π -stacking distance, which would result in a larger reorganization energy for the charge recombination process. As a consequence of the larger value of k_{cs} and smaller value of k_{cr} for the GG step versus an isolated guanine, the GG step can function as a shallow hole trap.

Intercalated acceptors

Tanaka and coworkers [148a,b] have investigated DNA-mediated electron transfer in a series of synthetic duplexes which possess the acridinium salt AC^+ attached to an L-threoninol residue with a tetramethylene tether at a defined site in an oligonucleotide conjugate. Duplex formation with a complementary strand possessing an adenine opposite the modified residue is proposed to result in AC^+ intercalation with expulsion of adenine from the duplex to an extrahelical location (Figure 15a,b). In the absence of nearby G:C base pairs, the intercalated AC^+ has a fluorescence quantum yield of 0.66 and a decay time of 22.8 ns. In view of the high calculated singlet-state reduction potential of AC^+ ($E^S = 2.69 \text{ eV}$, $E_{rdn} = -0.73 \text{ V}$, $E^S_{rdn} = 1.96 \text{ eV}$) it is surprising that isoergonic oxidation of adenine (see Table 3) is not observed. Both the quantum yield and decay time are reduced by c. 98 % by the presence of a G:C base pair on either side of the acridine. The extent of quenching of AC^+ by guanine decreases rapidly with the number of A:T base pairs intervening between acridine and guanine, c. 60 % quenching being observed for one A:T base pair and <5 % quenching for two A:T base pairs. The quantum yield and lifetime data provide values of $\beta = 1.5 \text{ \AA}^{-1}$ and $k_o = 1.9 \times 10^{12} \text{ s}^{-1}$.

Barton and coworkers [47, 149] have recently investigated fluorescence quenching

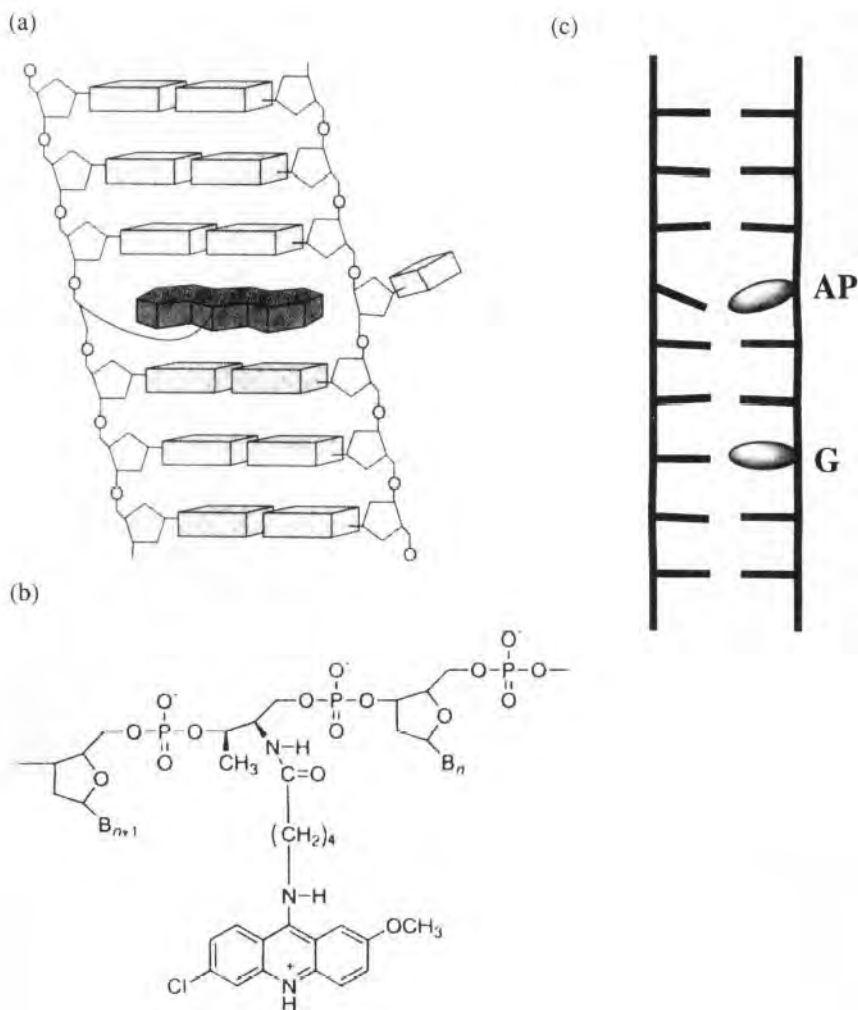

Figure 15. (a) Diagram of a duplex containing an intercalated acridine dye with an extrahelical adenine and (b) structure of the acridine conjugate [148]. Copyright 1999, with permission from Elsevier Science. (c) Diagram of a duplex containing an aminopurine (AP) and single guanine (G) [30].

in duplexes formed between an oligonucleotide containing ethidium (ET^+) tethered to the 5'-end with a complementary oligonucleotide containing the readily oxidized base deazaguanine (Z) located at a variable distance from the 3'-end. Very long tethers (consisting of chains of 14–16 atoms) are necessary to provide strong intercalation which is proposed to occur near the point of attachment. The extent of ET^+ fluorescence quenching by Z is found to decrease as the number of base pairs between Z and the most probable location for ET^+ is increased, c. 70 % quenching being observed for two intervening base pairs and <5 % quenching for six inter-

vening base pairs. There is no corresponding decrease in the fluorescence decay times, dual exponential decay with decay times of c. 9 ns and 2–3 ns being observed both in the absence and presence of Z.

The observation of intensity but not lifetime quenching was attributed to a component of ultrafast (static) electron transfer. In order to distinguish between the distance dependence of static electron transfer and the results of dynamic measurements, Barton has used the term γ to define the distance dependence of the fluorescence quantum yield data. Values of $\gamma = 0.33$ and 0.20 \AA^{-1} were obtained for two duplexes having different bases adjacent to Z [47]. A substantial decrease in the quenching efficiency was observed when the base-paired partner for Z was changed from C to T, A, or G. These observations establish that the fluorescence intensity of ET^+ in these duplexes is sensitive to the location of Z, the neighboring base pairs, and the presence of mismatches.

The dynamics of ethidium singlet-state decay have been studied by Wan et al. [149] using femtosecond transient absorption and fluorescence up-conversion for duplexes in which the donor Z is located at the 5th, 6th or 7th base pair. A 1–10-ps decay component is observed both for systems containing Z and those in which it is absent (and thus presumably do not undergo electron transfer). A second 75–100-ps component is also observed for the duplexes containing Z. In addition, significant nanosecond decay components are observed both in the absence and presence of Z, in accord with the results of Barton's previous study [47]. The two picosecond components of the singlet-state decay for the $\text{ET}^+\text{-B-Z}$ systems are assigned to distance-independent ultrafast electron transfer. However, transient absorption spectra of the products of electron transfer have not been reported, and thus these assignments should be viewed as tentative.

Modified nucleotide acceptors

Kelley and Barton [30] have recently investigated the fluorescence quenching of the adenine analogues EAD and AP (Table 4) by G and Z (Table 3) in ds DNA. The results of bimolecular quenching of EAD and AP by mononucleotides are discussed in Section 5.2.3 (p. 123). Fluorescence quantum yields and decay times were determined for duplexes containing EAD or AP as the electron acceptor and a single G or Z base as the electron donor (Figure 15c). The fluorescence quantum yield for an EAD-containing duplex in the absence of G or Z is smaller than that for the EAD nucleoside in water ($\Phi_f \sim 0.3$ versus 0.56) and the fluorescence decay times are shorter (dual exponential decay with decay times of 0.77 and 7.3 ns versus 23.8 ns for the EAD nucleoside). Thus relatively slow quenching of singlet EAD by neighboring A:T base pairs may occur. The presence of a G adjacent to EAD in the same strand results in a substantial decrease both the fluorescence intensity and decay times. An adjacent AG sequence results in partial quenching, and an AAG sequence in only slight quenching. These results are qualitatively similar to those reported by Tanaka and colleagues [148a,b] for intercalated acridine; however, the value of β calculated by Kelley and Barton from their quantum yield data is somewhat smaller than that reported by Tanaka (1.0 versus 1.4 \AA^{-1}).

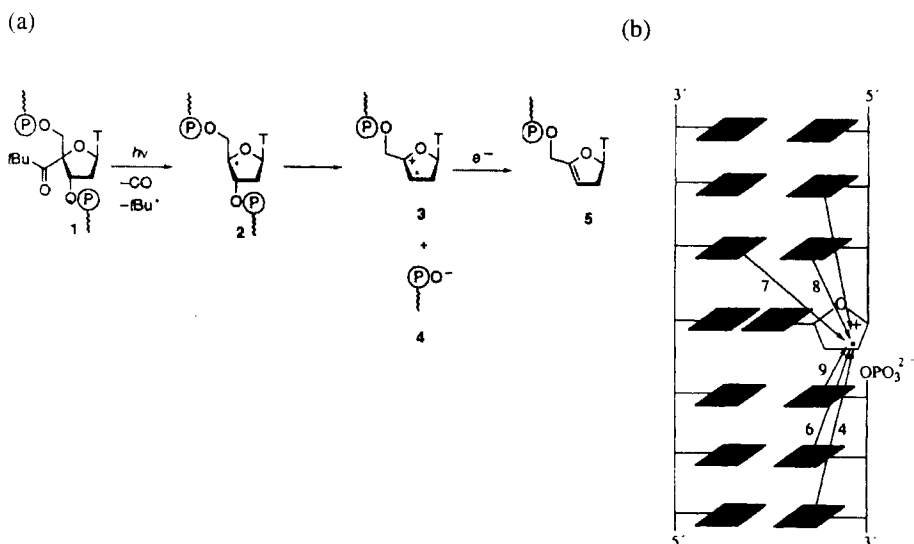

Kelley and Barton [30] have also investigated quenching of the fluorescence

intensity of AP by G and Z by duplex DNA. In the absence of a neighboring G or Z, they observe low fluorescence quantum yields ($\Phi_f < 0.07$), indicative of extensive quenching by neighboring A:T base pairs. As noted in Section 5.2.3, the fluorescence of AP is extensively quenched in alternating AP-T and AP-U copolymers which lack strong donor bases [29a], and the fluorescence decay of AP in duplex DNA is multiexponential with decay times ranging from 50 ps to 9 ns [29d,e]. Kelley and Barton [30] report that introduction of a G or Z base near AP in the same strand of a synthetic duplex results in a decrease in AP fluorescence intensity, but little change in the dual exponential fluorescence decay times measured with a time resolution of c. 0.1 ns. This could result from quenching of the shortest-lived fully stacked ground-state conformations, but no quenching of the less-well stacked conformations [29d,e]. Analysis of the distance dependence of the fluorescence intensity quenching provides γ (p. 151) values of 0.4 and 0.6 Å⁻¹ for quenching of AP by G and Z, respectively.

Kelley and Barton [30] have also investigated quenching of the fluorescence of EAD and AP by G and Z when the donor and acceptor are located in different strands. In the case of EAD, little quenching is observed; in the case of AP, quenching of both the fluorescence intensity and the shorter-lived decay component is observed. Analysis of the quantum yield data provides values of $\gamma = 0.1$ and 0.4 Å⁻¹ for quenching of AP by G and Z, respectively. It is interesting to note that strand-selective quenching is observed for these nucleobase analogues which are located in a specific strand, but not for Tanaka's acridinium intercalator [148] or our stilbene-linked hairpins [110] in which the acceptor overlaps with both strands.

An ingenious indirect method of investigating the distance dependence of electron transfer in DNA based on the relative yields of competing chemical processes has been developed by Giese and coworkers [150]. As outlined in Scheme 1a, irradiation of a 4-acylated thymidine (T*) incorporated into an oligonucleotide **1** results in α -cleavage to yield the radical **2** which undergoes spontaneous cleavage to yield the cation radical **3** and the phosphorylated oligonucleotide **4**. The cation radical can be reduced to yield **5** via electron transfer from a GGG hole trap located at varying distances from the labeled T* (Scheme 1b), leading to further cleavage of the oligonucleotide or reaction with water to form products derived from the cation radical **3**. The relative rates for the electron transfer and trapping processes can be obtained from yields of strand cleavage products using the expression: $k_{et}/k_{water} = [5]/([4] - [5])$. Assuming that the pseudo first-order rate constant k_{water} is independent of base sequence, this ratio provides the relative rates of electron transfer from GGG to the cation radical **3**. Analysis of the data obtained for six different duplexes provides a value of $\beta = 1.0 \pm 0.15$ Å⁻¹.

Meggers et al. have modified the approach outlined in Scheme 1 by placing a guanine adjacent to the acetylated thymine [150b]. This results in rapid primary hole transfer from the deoxyribose to the adjacent guanine. The efficiency of secondary hole transfer processes from G⁺⁺ to a GGG hole trap can then be determined as a function of the number of base pairs separating the G⁺⁺ and GGG sites. The efficiency of strand scission at the GGG site is found to decrease as the number of AT base pairs separating the G⁺⁺ and GGG sites increases. A plot of the relative rate of hole transfer versus the distance provides a value of $\beta = 0.7$ Å⁻¹.

Scheme 1. (a) Mechanism for photochemical formation of cation radical 3 and (b) electron transfer from neighboring guanines to the radical cation [150a].

There are several advantages of the approach outlined in Scheme 1. First, the presence of the acetylated base should not perturb duplex base stacking. Second, the cation radical 3 is formed irreversibly, which precludes competition of charge recombination with charge migration. Third, the cation radical 3 is a putative intermediate in the oxidative cleavage of DNA under biological conditions. An obvious limitation of this approach is its failure to provide direct kinetic information for the charge migration processes.

5.3.4 Summary of Results for Single-Step Electron Transfer

Values of k_0 and β for DNA-mediated electron transfer in systems where distance-dependent kinetic data is available are summarized in Table 8. Somewhat higher values of k_0 were obtained in Harriman's [129, 130] studies of randomly intercalated donors and acceptors than in the studies of (T:A)_n-mediated oxidation of guanine by Lewis [110a,b] and Tanaka and colleagues [148]. This might result from errors in data extrapolation to zero distance, difference in bridge base pair sequence, or differences in acceptor–bridge interactions. The values of β are in the range 0.66 to 1.49 Å⁻¹. A value near the low end of this range ($\beta = 0.70$ Å⁻¹) has also been obtained by Meggers et al. [150b] from analysis of strand cleavage efficiencies. Values near the high end of this range are typical of proteins [121], whereas values near the low end are more typical of conjugated polyenes [124].

According to Eq. 17, the value of β should depend upon ΔE , the energy gap between the initial and bridge states (see Figure 12, p. 140), and t_{nm} the electronic

coupling matrix element between bridge states. Grozema et al. [153] have reported that the calculated value of β for an AT bridge increases from c. 0.5 to 1 \AA^{-1} as ΔE increases from 0.4 to 0.7 eV . In the case of Meggers' data [150b], ΔE should equal the difference in oxidation potentials for G versus A, which we estimate to be $\sim 0.5 \text{ eV}$. Based on the singlet-state reduction potentials of ET^+ and SA, values of $\Delta E = 0.7$ and 0.2 eV , respectively, can be estimated for these systems, in accord with the smaller value of β for the SA hairpin system [110, 129]. Small values of ΔE ($< 0.2 \text{ eV}$) are also expected for the acridinium acceptor used by Fukui et al. [148b] and the EAD acceptor used by Kelley and Barton [30] in their studies of electron transfer mediated by $(\text{T:A})_n$ base pairs. Kelley and Barton [30] suggest that a large value of β for the EAD/G system might reflect poor orbital overlap between EAD which cannot adopt a normal π -stacked geometry and the adjacent base pairs. Information about the geometry of the acridinium/G system studied by Fukui et al. [148a,b] is not available.

The reader may desire an explanation of the low values of γ derived by Barton and coworkers [30, 131, 137–140] from fluorescence quenching data for systems in which the dynamics of electron transfer have not been directly measured. In most cases, the absolute efficiency (quantum yield) of the quenching processes studied in these systems is rather low, and thus they may represent long-range electron transfer by mechanisms other than superexchange, such as to those described by Felts et al. [125], Davis and colleagues [126], and Okada et al. [127]. However, the author considers that it is highly unlikely that such processes occur with rate constants $> 10^9 \text{ s}^{-1}$. In view of the complex nature of these systems, the author is loath to offer a detailed interpretation, and refers the reader to commentaries by others who have been directly involved in this research [13, 15].

5.4 Photoinitiated Charge Transport in DNA

5.4.1 Background

As described in Section 5.3, photoinduced electron transfer in DNA via a single-step superexchange mechanism is strongly distance-dependent (Eq. 16). The available kinetic data suggest that electron transfer can compete effectively with excited-state decay pathways of singlet acceptors over no more than four or five base pairs. However, data from pulse radiolysis investigations (Section 5.1.3) and studies of photoinitiated DNA strand cleavage (Section 5.4.2) indicate that electrons can migrate over distances substantially longer than several base pairs. Based on strand cleavage studies, Breslin, Schuster and colleagues [151a,b] suggested in 1996 that electron transfer over long distances in DNA might occur by an alternative hole-hopping mechanism.

An energy level scheme for photoinitiated hole hopping in DNA is shown in Figure 16. Photoinduced electron transfer between the singlet acceptor and the nearest guanine, creates the initial hole on guanine, which can then undergo

Figure 16. Energy level diagram for photochemical charge separation and charge recombination via a hole-hopping mechanism for an acceptor–bridge–donor system.

reversible hopping steps until the hole trap consisting of a GG or GGG step is reached. In this scheme, hopping must compete with charge recombination. However, Meggers' method of irreversible photogeneration of a guanine cation radical (Scheme 1) avoids this competition [150]. The use of triplet acceptors in combination with oxygen as an anion radical scavenger can also circumvent competing charge recombination [151]. Since GG is a shallow hole trap (Section 5.3.3), hole hopping between multiple GG steps can also occur.

The theoretical basis for hole hopping and electron transport in DNA was investigated as early as 1974 by Dee and Baur [152]. Recently, Jortner and colleagues [120, 154] have proposed that hole hopping could be treated as a series of hops between guanines, with each hop treated as a superexchange process. According to this theory, the efficiency of a process involving N equal hopping steps can be described by Eq. 19,

$$\Phi \propto \exp[-N(k_d/k_{\text{hop}})^{1/2}] \quad (19)$$

where k_{hop} is the hole-hopping rate constant for each hopping step, and k_d is the rate constant for chemical processes of the guanine cation radicals which compete with hole hopping (Scheme 2, $k = k_{\text{hop}}$). This equation can be written in the form of Eq. 16 for superexchange electron transfer to provide Eq. 20,

$$\Phi \propto \exp(-\beta'R) \quad (20)$$

where β' is a characteristic of the system, and R is the donor–acceptor distance. In view of the longer distances over which hole hopping take place, static and dynamic disorder are likely to be even more important than they are for shorter distance

electron transfer processes. Quantum mechanical hopping models have been used successfully by several groups to correlate theory with experiment, and will be discussed in Section 5.4.4 [153–155].

Henderson et al. [41] have proposed a modified version of the hole-hopping mechanism which accounts for the conformational flexibility of DNA and for changes in geometry which most likely accompany introduction of a cation radical into the π -stacked duplex structure. This mechanism, described as “phonon-assisted polaron-like hopping”, is shown schematically in Scheme 3. According to this proposal, polaron formation is the consequence of a local structural distortion that delocalizes the cation radical over several adjacent bases. The polaron migrates by a thermally activated hopping process with hop lengths that are dependent upon the base sequence. The distance dependence of the charge migration process is thus determined by the relative rates of hopping (k_h), charge annihilation (k_a), and chemical trapping processes (k_t) which ultimately lead to strand cleavage.

5.4.2 DNA Cleavage and Thymine Dimer Repair over Long Distances

DNA cleavage

Single-strand cleavage of duplex DNA has been observed in the presence of a variety of photochemical oxidants [6, 7]. Cleavage occurs selectively at the 5'G of GG steps, with lower reactivity observed for isolated guanines. This pattern of cleavage is different from that for photonucleases which operate by a free radical or singlet oxygen mechanism. Transient absorption spectroscopy has provided evidence for electron transfer from a nucleobase to the excited oxidant as the initial step in the strand cleavage process. Treatment of the irradiated duplex with hot piperidine is, in most cases, necessary in order to observe strand cleavage. The chemical reactions leading to strand cleavage are complex and not fully elucidated. Reaction of the

Scheme 3. Phonon-assisted polaron-like hole hopping. Reprinted with permission from ref. 161c. Copyright 1999 American Chemical Society.

guanine cation radical with either water or oxygen is proposed to be the initial chemical reaction, leading to the formation of 8-oxo-G. However, 8-oxoG must undergo further chemical processes in order for strand scission to be observed. Quantum yields for the overall process have been reported in only a few cases. The low values ($<10^{-3}$) could result from inefficiencies in: (a) the initial electron transfer processes leading to formation of the reactive guanine cation radical; (b) chemical reactions of the guanine cation radical; and (c) the piperidine-promoted strand cleavage process.

Photoinduced cleavage at the GG step of a 6-mer by a nontethered triplet naphthalimide was proposed by Saito et al. [83] to be initiated by a contact electron transfer process (Section 5.2.4). Schuster's initial studies of oxidative cleavage by nontethered triplet anthraquinone (AQ) led to the suggestion that GG oxidation might occur indirectly, via oxidation of any of the nucleobases followed by hole migration from the primary electron donor to a GG hole trap [151]. This suggestion was supported by the observation of efficient cleavage at all seven GG steps of a 248-bp restriction fragment by a randomly intercalated anthraquinone acceptor. The observation of cleavage in these reactions requires the presence of oxygen. Electron transfer from AQ^- to oxygen presumably prevents charge recombination with guanine cation radicals.

In a benchmark 1996 letter to *Nature*, Barton and colleagues [156] reported that 365-nm irradiation of a duplex which possesses an end-tethered intercalating $Rh(\phi)_2bpy^{+3}$ complex in one strand and two GG steps in the complementary strand (Figure 17a) results in cleavage at both the proximal and distal GG steps. Since the distal 5'G is located 10 bp from the locus of intercalation, long-range electron transfer clearly occurs in this duplex. Two possible mechanism for this process were discussed: concerted long-range electron transfer; and oxidation of a base near the intercalated acceptor followed by hole migration to the two GG steps. Subsequent investigations of duplexes possessing a tethered $Rh(\phi)_2bpy^{+3}$ photo-oxidant showed the ratio of distal/proximal cleavage decreased only slightly from c. 1.2 to 1.0 as the separation between the proximal and distal GG steps increased from 6 to 15 bp [157a]. This ratio is also relatively insensitive to the base pair sequence between the GG steps. However, the distal/proximal ratio decreases when a base bulge is present between the GG steps, from 1.2 in the absence of a bulge to c. 0.5 in the presence of a TTT bulge [157b]. The distal/proximal ratio was also observed to decrease upon complex formation with a protein that binds to the base sequence separating the two GG steps [157d]. This decrease was attributed to a protein-induced distortion of DNA base stacking.

Barton and coworkers [158] have also employed the flash-quench technique to study to oxidative cleavage of duplexes in which one strand contains a tethered 5'- $Ru(phen)_2dppz^{2+}$ complex and the complementary strand contains one or more GG step. Strand cleavage occurs selectively at the 5'G of a GG step located 11 bp from the locus of $Ru(II)$ intercalation in the presence of an electron acceptor such as $Ru(NH_3)_6^{3+}$ or methyl viologen (MV^+ ; Table 5). Excitation of the intercalated $Ru(II)$ complex followed by diffusional or static quenching by the added acceptor generates the powerful oxidant $Ru(III)$. In the absence of a GG step, oxidation occurs at all single guanines with comparable efficiency. The presence of a mis-

matched GA or GT base pair between the locus of intercalation and the GG step results in a pronounced decrease in the efficiency of strand cleavage. Photoinduced cleavage at both proximal and distal GG steps has also been observed for a duplex which possesses a 5'-tethered ethidium in one strand, and two GG steps in the complementary strand [117].

Gasper and Schuster [159] have investigated photoinduced strand cleavage in

duplexes which incorporate an end-stacked anthraquinone linked covalently to the 5'-terminus on one strand and possess two or more GG steps in the complementary strand (Figure 17b). They observe cleavage with comparable efficiency at GG steps located 7 and 12 bp from the anthraquinone. Neither the proximal GG step nor an abasic site between the two steps inhibits cleavage at the distal GG site; however, an 8-oxoguanine (OG; Figure 1) in the proximal site does inhibit cleavage at the distal GG site. Evidently, OG functions as a more effective hole trap than the proximal GG. This could result from either slow hole transport from OG^+ to the distal GG or rapid chemical reactions of OG^+ . Similar results have recently been reported for duplexes in which an intercalated anthraquinone is tethered at mid-strand with two GG steps on either side [160]. In this case, more cleavage is observed at the proximal versus distal GG steps; however, there is little preference for cleavage on the 3' versus 5' side of the anthraquinone. Replacement of one of the proximal GG steps by OG inhibits distal cleavage, but has no effect on cleavage on the other side of the intercalator. Experiments in which the GG steps and OG were placed in complementary strands provided evidence that strand-to-strand hopping occurs, but is less efficient than migration along a single strand.

End-stacked tethered anthraquinones have also been employed to investigate long-distance cleavage at GG steps in structures other than standard B-form DNA [161]. Cleavage in single-stranded overhangs has been studied using complementary strands which contain GG steps both in the duplex and single-strand regions [161a]. Comparable efficiency is observed in both regions, leading to the proposal that coiling in the single-strand region brings the GG steps into close contact. In a study of DNA structures with GG steps in both triplex and duplex regions it was found that charge migration occurs through the triplex region, but that strand cleavage is less efficient in triplex versus duplex regions [161b]. Diminished reactivity in the triplex region was attributed to a structure which inhibits reactions of the GG cation radicals with water. Similarly, charge migration is observed to occur in the A-form helices of RNA/DNA hybrids, but strand cleavage is much less efficient than in B-form DNA [161c]. Long-range hole migration is also observed in PNA/DNA duplexes [161d].

Thymine dimer repair

Model studies of photochemical repair of the thymine [2 + 2] photodimer have shown that both oxidation and reduction can result in cycloreversion via a radical ion mechanism [162]. Barton and coworkers [163a,b] have investigated the photo-initiated repair of duplexes containing thymine dimer sites using both nontethered and tethered Rh(III) complexes as photooxidizing agents (Figure 17c). The quantum yield for photorepair of a Rh(III)-tethered duplex is 2×10^{-6} , approximately 30 times lower than for photorepair using nontethered Rh^{3+} . It is possible that the exceptionally low quantum yield reflects a hole-hopping mechanism in which charge recombination of an oxidized base with Rh(II) is much more efficient than hopping to the thymine dimer site and dimer cleavage.

The repair efficiency in this system increases as the distance between thymine dimer and intercalated Rh(III) complex is increased from 4 bp to 6 bp, but decreases in the presence of base bulges between the dimer and intercalator. Subse-

quent investigation of duplexes containing a tethered Rh(III) intercalator in one strand and both a thymine dimer and GG step in the complementary strand showed that dimer repair and GG cleavage both occur. The yield of dimer repair is >10 times that of GG damage. Since the GG site has a lower oxidation potential than a thymine dimer, selective dimer repair presumably reflects a faster rate for dimer cycloreversion than for the reactions of $\text{GG}^{+\bullet}$ that lead to strand cleavage.

5.4.3 Distance-Dependent Hole Migration in DNA

Strand cleavage studies

In their studies of distance-dependent strand cleavage in DNA, Giese and colleagues [150a,b] found that three or four AT base pairs separating the photochemically generated deoxyribose or guanine oxidant and a GGG trap site were sufficient to totally inhibit oxidative cleavage at the trap site (Section 5.3.3, p. 152; see also, Scheme 1). In addition, they made the remarkable observation that oxidative cleavage could be observed over much longer distances when a combination of AT and GC base pairs separated the $\text{G}^{+\bullet}$ and GGG sites. Thus more efficient cleavage at GGG was observed for a four-base pair sequence containing a single GC base pair than for a three-base pair sequence containing only AT base pairs. Relative yields for a series of duplexes containing one, two or four repeating TTG sequences between the $\text{G}^{+\bullet}$ and GGG are reported and shown in Figure 18 [150c]. A plot of $\ln(\Phi_{\text{rel}})$ versus R according to Eq. 20 provides a slope $\beta' = 0.07 \text{ \AA}^{-1}$, significantly smaller than those for DNA-mediated superexchange electron transfer (Table 8). Also shown in Figure 18 is the relative efficiency of GGG cleavage for a duplex possessing a 15-bp sequence containing alternating AT and GC base pairs with guanines located in both strands. Cleavage is seen to be more efficient for this duplex than for shorter duplexes having the TTG repeat sequence. Thus, it appears that hole hopping is not constrained to occur in a single strand, and is more efficient when the distance between hops is shorter.

Núñez et al. [157a] have recently reported the results of photoinduced cleavage of 63-mer duplexes which contain a 5'-tethered Rh(III) or Ru(II) complex in one strand and six GG base pairs in the complementary strand (Figure 19a). Direct irradiation of the Rh^{3+} duplex or irradiation of the Ru^{2+} duplex in the presence of methyl viologen followed by piperidine treatment results in cleavage at all six GG steps. Unlike earlier studies where distal/proximal cleavage ratios greater than 1.0 were observed [156–158], proximal cleavage is more efficient than distal cleavage in these systems. The relative efficiency of cleavage at longer distances was observed to be greater for the Rh(III) versus Ru(II) system, and to increase with increasing temperature. These results were interpreted in terms of a hole-hopping mechanism in which the GG steps serve as electronically coupled “stepping stones.” It was further suggested that hopping might occur between “delocalized base domains,” rather than between discrete base positions.”

Similar results have been reported by Schuster and coworkers [41, 160] for a 60-mer duplex possessing a tethered 5'-anthraquinone in one strand and four GG steps

Figure 18. Relative efficiencies of strand cleavage at a GGG site following charge migration via hole hopping from *G [150].

in the complementary strand and for a 71-mer possessing seven GG steps in the complementary strand (Figure 19b). In both cases the efficiency of strand cleavage was found to decrease with increasing distance between the GG and the end-stacked anthraquinone. A plot of $\ln(\Phi_{\text{rel}})$ versus distance has a slope $\beta' = 0.02 \text{ \AA}^{-1}$ for both duplexes, even smaller than the value obtained by Giese et al. [150c].

A closely related approach to the study of hole hopping in DNA was recently reported by Nakatani et al. [164] using a modified nucleobase in which a strong electron acceptor, cyanobenzophenone, is covalently attached to 2'-deoxyuridine (BP-U) by means of a rigid acetylene linker (Figure 19c). The efficiency of strand cleavage at a GG trap site was determined as a function of the base sequence between BP-U and the GG trap. It was found that a single guanine primary electron donor located in the base pair immediately adjacent to the BP-U was necessary in order to observe cleavage at a remote GG trap site. The presence of a single AT base pair between the BP-U and primary G donor results in a marked decrease in remote GG cleavage. The efficiency of GG cleavage is also dependent upon the base sequence separating the primary G donor and the GG site. A 5'TGTGTA3' sequence is able to mediate hole transfer, but a 5'TATATA3' sequence is not, in accord with Giese's observation that three or more AT base pairs effectively block hole transfer [150]. When two GG steps are present in the same strand separated by two AT base pairs, cleavage is observed at both the sites with a distal/proximal ratio of 0.83, similar to the value observed by Barton and coworkers [156–158].

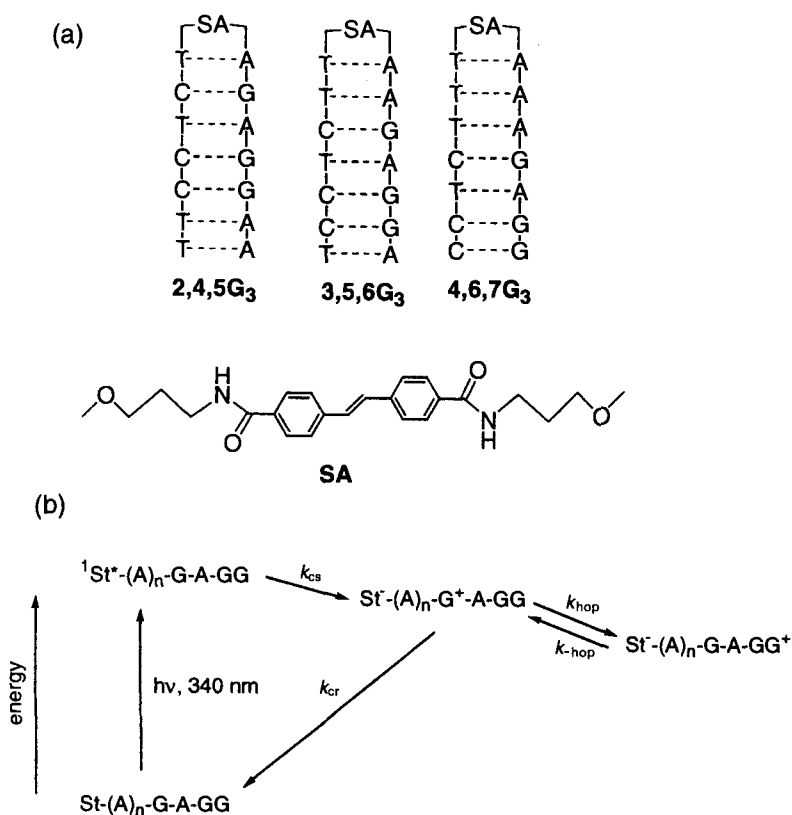

Figure 20. (a) Structures of hairpins containing an GAGG sequence separated from the SA acceptor by 1–3 A:T base pairs. (b) Kinetic model for the hole-hopping process.

Dynamics of hole hopping

The stilbene-linked hairpins used by Lewis and coworkers to investigate the dynamics of charge transfer and recombination in DNA (Section 4.3.3) contain a single G:C base pair (see Figure 10). These structures can be modified by the introduction of an AGG sequence adjacent to the G:C base pair (Figure 20a) [165]. The occurrence of hole hopping from the initially oxidized G to the GG step should not affect the dynamics of charge separation. However, a new long-lived component should be observed for the decay of the stilbene anion radical ($\text{St}^{\cdot-}$) if hole hopping competes successfully with charge recombination. In the case of the hairpins 3,5,6G₃ and 4,6,7G₃, but not 2,4,5G₃, new long-lived decay components are observed in accord with the occurrence of hole hopping.

Analysis of the transient decay data using the kinetic model shown in Figure 20b provides a rate constant of $k_{\text{hop}} = 1.0 \pm 0.5 \times 10^8 \text{ s}^{-1}$ for the hole-hopping processes in the hairpins 3,5,6G₃ and 4,6,7G₃. This rate is consistent with the failure of hole hopping to compete with charge recombination in 2,4,5G₃ ($k_{\text{cr}} = 1.0 \times 10^{10} \text{ s}^{-1}$). It

is also much too slow to compete with charge recombination in contact singlet ion pairs (Section 5.2.3). However, it is consistent with the ability of hole-hopping processes to compete with slower chemical reactions of G^+ . The kinetic analysis also provides the rate constant for the return process of $k_{-\text{hop}} = 5 \pm 1 \times 10^6 \text{ s}^{-1}$. The ratio $k_{\text{hop}}/k_{-\text{hop}} \sim 15$ is consistent with the observation that oxidative cleavage of DNA occurs predominantly at GG (or GGG) steps, but that GG steps do not inhibit further hole migration. When the AGG sequence in the hairpin 3,5,6G₃ is replaced with either a TGG or a AAGG sequence, no long-lived decay components are observed. Evidently hole hopping across T or AA is much slower than charge recombination in these hairpins ($k_{\text{cr}} \sim 5 \times 10^8 \text{ s}^{-1}$).

Theoretical analysis of hole hopping

The data of Giese and coworkers [150] for the distance and sequence dependence of strand cleavage has been analyzed by three groups. Grozema et al. [153] investigated two theoretical models: a quantum mechanical charge migration model based on the tight binding approach; and the Miller–Abrahams model of incoherent hopping. The former, but not the latter, was found to be consistent with Giese’s data.

Bixon et al. [154] analyzed Giese’s data for the sequence $G^+(\text{TTG})_N\text{GGG}$ using the kinetic model of Scheme 2 and obtained the parameters $k_r/k \sim k_d/k = 0.08$ and $k_t/k \sim 1$. An estimate of $k \sim 10^9 \text{ s}^{-1}$ for hole hopping mediated by two TA base pairs was calculated using superexchange theory (Eq. 11). This value is higher than the experimental value of $k \sim 10^8 \text{ s}^{-1}$ for hole hopping mediated by a single AT base pair. Estimates of k_r based on experimental data are in the microsecond time domain [64, 150a], much slower than the value of $k_r \sim 10^8 \text{ s}^{-1}$ calculated by Bixon et al. [154]. The reasons for these discrepancies remain to be clarified.

The analysis of Giese’s data by Berlin et al. [155] provides a similar value of $k_d/k = 0.11$ and a value of the distance dependence of hole transport $\beta' \sim 0.1 \text{ \AA}^{-1}$. This value is c. 10-fold smaller than the values of $0.6 < \beta < 1.4$ obtained for superexchange electron transfer in accord with the dominance of the hole-hopping mechanism at large D–A distances. By using a combination of hole hopping over several guanines and superexchange between neighboring guanines, both Bixon et al. [154] and Berlin et al. [155] have obtained excellent agreement between calculated and observed relative rate constants.

5.5 Conductivity of Ionized DNA Assemblies

5.5.1 Background

The idea that a “ π -electron ... can traverse the entire length of a polynucleotide helix along its axis” was advanced by Eley and Spivy in 1962 [10]. While this suggestion has been much quoted, it seems based on questionable d.c. conductivity data. Similar conductivities were observed for several samples of “dry” DNA,

RNA, and proteins when compressed between platinum electrodes. Subsequent studies have established that proteins and ss DNA or RNA do not function as molecular wires; however, the conductivity of ds DNA remains the subject of debate. Recently there have been several studies of DNA conductivity in fibers, single crystals, aligned films, and monolayer assemblies. Far from resolving the controversy, they seem to have intensified it.

An early attempt to calculate the mobility of electrons and holes in ds DNA using SCF LCAO molecular orbital methods was reported by Dee and Bauer [152]. They assumed that charge migration occurred via site-to-site interaction between neighboring base pairs rather than via long-range quantum mechanical tunneling. Their calculated value of the electronic conductivity along the helix axis is c. $10^{-4} \Omega^{-1} \text{ cm}^{-1}$, “more nearly like that of a weak inorganic semiconductor than that of an organic molecular crystal.”

5.5.2 DNA Fibers and Single Molecules

The radiation-induced conductivity in hydrated samples of aligned versus non-aligned solid DNA fibers was compared by Warman et al. [166]. The dry fibers were found to be essentially nonconducting, as a water content of 10–15 waters per base pair is necessary to observe conductivity. Under these conditions, the conductivity of the aligned and nonaligned films was found to be similar. It was concluded that conductivity in solid B-DNA “is due to highly mobile charge carriers within the outer mantle of the biopolymer chains rather than within the base-pair cores.”

Bernhard and colleagues [167] have investigated the generation of radical ions in crystalline DNA by means of X-radiation with EPR detection at 4 K. A radical ion density corresponding to one radical ion per 57 bp was observed for single crystals of both A-form and B-form DNA. Similar results were observed for DNA films and powders and a crystalline protein. From this they concluded that holes and electrons are trapped on guanine and cytosine, respectively at 4 K and that, above 80 K, migration of electrons and holes is propagated by hopping between shallow traps. The decrease in conductivity at low temperatures is characteristic of an insulator rather than a conductor.

Fink and Schönenberger [168] have studied the electrical conduction of small DNA ropes consisting of a few molecules under high vacuum conditions by employing a modified low-energy electron point source microscope. A single rope which spans a 2- μm hole in a gold-plated carbon foil is broken with a manipulation tip, and its conductivity probed by applying an electrical potential between the tip and carbon foil. DNA ropes that are 600 nm long display no charging, and a single molecule of DNA is found to have a low estimated resistance. From these studies, it is concluded that the electronic transport mechanism must be of an electronic nature rather than ionic conduction, as proposed by Warman et al. [166]. However, the mechanism of charge transport remains unclear. The authors point out that any molecule attached to the DNA by an ionic or covalent bond (including the π -stacked nucleobases) could affect the conductivity.

Recently, the current generated when voltage is applied to one (or several) 30-mer

polyG-polyC duplex suspended between two metal nanoelectrodes has been measured by Porath et al. [169]. The current is essentially zero below a threshold voltage of several volts, consistent with the behavior of a Y-gap semiconductor. At higher voltages the current rises sharply showing that DNA can transport charge carriers. The observed voltage gap is concluded to be incompatible with either a single-step electron transfer process or with hopping models, and it is concluded that electronic interactions between the bases lead to a molecular band in which the electronic states are delocalized over the entire length of the molecule. It would be interesting to determine if duplexes with alternating purine and pyrimidine bases displayed similar behavior.

Duplex DNA has been used as a template for the fabrication of a nanometer-scale wire by Braun et al. [170]. Using molecular assembly methods, they attached a single 12 μm -long duplex to two gold electrodes by means of gold-sulfur bonding. Exchange of Ag^+ ions for Na^+ followed by solution chemical “developing” provided a 100 nm-wide conductive wire consisting of metallic silver aggregates bound to the DNA skeleton. The current was found to be carried solely by the silver deposited on the DNA template.

5.5.3 Thin Films and Monolayer Assemblies

The electric conductivity of cast films prepared from a precipitated ds DNA-lipid complex which has a 1:1 ratio of phosphate groups to cationic amphiphile has been studied by Okahata et al. [171]. The conductivity in stretched films put on a comb-shaped electrode is highly anisotropic, having a substantially larger value when the DNA strand axis is perpendicular to the gold electrodes than when it is parallel. Little or no conductivity is observed for an unstretched film or for a DNA-lipid cast film prepared from ss poly(dA). Photoinduced conductivity was observed after soaking the aligned films of the ds, but not the ss film, in a solution of acridine orange. Based on the conductivity of the films prepared from ds, but not ss DNA, these authors conclude that the photocurrents pass through the stacked base pairs of the aligned DNA strands in the films. However, ionic transport by a mechanism similar to that proposed by Warman et al. [166] would also require the more rigid structure of ds DNA, and evidently was not considered.

Both ss and ds oligonucleotides have been attached to electrode surfaces using a variety of covalent linkages [172–174]. Napier et al. [172] have developed sensors for specific base sequences by attaching a complementary ss oligonucleotide to a polymer-coated electrode surface via amide linkages. Upon hybridization, the duplex will bind electroactive small molecules which associate with the duplex and can be detected by electrochemical measurements or electrogenerated chemiluminescence.

Barton and coworkers [173a–c] have attached ds oligonucleotides to gold surfaces by means of thiol-terminated tethers. The surface-attached ds DNA is proposed to form a densely packed monolayer in which the DNA helical axes are at an average 45° angle to the surface. The electroactive dye methylene blue intercalates in the surface-attached duplexes to form a 1:1 complex in which the dye is located at G:C-rich sites remote from the electrode surface [173a]. Cyclic voltametry of the

DNA–dye assemblies provided a nearly reversible response at scan rates up to 500 mV s^{-1} . Thus, electron transfer through the ds DNA and hexamethylenethiol linker was concluded to be fast on the electrochemical time scale. Similar conclusions were drawn from the cyclic voltametry of the electroactive intercalator daunomycin selectively bound to G:C sites at varying locations within a duplex attached to the electrode surface with a 13-atom alkylamide tether [173c].

Hartwich et al. [174] have investigated electron transport through self-assembled monolayers of ss and ds oligonucleotides attached to a gold surface by means of a short alkanethiol linker. To the opposite end of the oligonucleotide the quinone PQQ (pyrrolo-quinoline-quinone) was attached by condensation after formation of the monolayer. The functionalized ds helices are proposed to be tilted at an angle of $30 \pm 10^\circ$ with respect to the gold surface. Voltametric waves for the diffusing $\text{Fe}(\text{CN})_6^{3-/4-}$ couple were observed for the ds, but not for the ss, monolayers. In addition, two mismatches in the 12-mer duplex are sufficient to significantly reduce the rate of electron transport through the ds monolayer. Anisotropic conduction is attributed to the concerted movement of cations in the direction of the ds helical axis when an electric field is applied. These workers conclude that their results, like those of Okahata et al. [171] and Fink and Schönenberger [168] are consistent with a doped ionic semiconductor model and speculate that oxidation of guanine may create a n-type dopant in ds DNA.

5.6 Conclusions and Prospects

Investigations of the dynamics of photoinduced electron transfer processes in DNA have revealed many of the important features of these processes. The excitation of a π -stacked singlet electron acceptor–nucleobase electron donor complex can result in ultrafast charge separation and charge recombination when charge separation is exergonic (Section 4.2). Rate constants for charge separation increase as ΔG_{et} becomes more exergonic (normal region), whereas rate constants for charge recombination decrease as ΔG_{et} becomes more exergonic (inverted region) [110–112], in accord with a superexchange mechanism (Eqs. 10 and 11). When the acceptor and nucleobase are not π -stacked, the rates of both charge separation and recombination are much slower due to the lower electronic coupling between the donor and acceptor, behavior characteristic of a solvent-separated radical ion pair [88].

Electron transfer processes can occur over longer distances when the π -stacked singlet acceptor is not quenched by the neighboring nucleobase (Section 4.3). Both exogenous donors and guanine (or more readily oxidized nucleobase analogue) have been used as the electron donors. In cases where dynamic information is available from time-resolved spectroscopy the rate constants for both charge separation and recombination are strongly distance-dependent [110, 130]. Values of the exponential distance-dependence parameter β lie in the range $0.6\text{--}1.4 \text{ \AA}^{-1}$ (Table 8), and depend upon both the acceptor–DNA electronic coupling and reorganization energy, in accord with a single-step superexchange mechanism (Eq. 16).

Evidence for long-distance electron transfer processes which are not strongly distance-dependent have been obtained from studies of fluorescence intensity quenching and photoinduced strand cleavage and thymine dimer repair (Section 4.4). Recent studies of the distance-dependence of DNA strand cleavage have provided evidence for a hole-hopping mechanism in which a photochemically generated hole can migrate from the locus of its generation to a remote GG or GGG step where strand cleavage occurs [41, 150, 157, 160]. Hole hopping is believed to involve guanine bases due to their low oxidation potentials, though other bases or ensembles of neighboring bases may be involved. Analysis of the relative strand cleavage efficiencies provides values of the distance-dependence $\beta' < 0.1$ (Eq. 20), in accord with a hole-hopping mechanism.

The efficiency of the hopping process is determined by the number of hops and the relative rates of hopping versus competing processes, which include charge recombination and chemical reactions of the guanine cation radicals. The first measurements of the dynamics of a hopping process provide a value of c. 10^8 s^{-1} for hopping from a guanine cation radical to a GG step across a single adenine [165]. Rapid charge recombination in radical ion pairs limits the efficiency of photo-initiated hole hopping using singlet acceptors. This limitation can be avoided by the use of triplet acceptors if intersystem crossing of the singlet precursor is more rapid than singlet charge separation [84]. Irreversible photogeneration of a cation radical has been used creatively in studies of hole transport in DNA [150], but cannot be used directly to provide information about dynamics.

Investigations of photoinitiated charge transport processes in DNA have thus far been limited to hole transport. Electron transport in DNA following reduction by solvated electrons (Section 4.1.3) has been observed to occur over multiple base pairs, although the dynamics of this process has not been investigated. Bixon et al. [154] have suggested that electron transport in DNA might be highly efficient if there is significant electronic coupling between thymine and cytosine bases, which have similar reduction potentials. A preliminary study of base pair photoreduction by a π -stacked singlet donor showed that both charge separation and recombination with neighboring base pairs is very rapid [26], as is the case for photooxidation of DNA [110]. No studies of long-distance photoinjection of electrons into DNA have been reported to date.

Investigations of electrical conductivity in single molecules and ensembles of DNA (Section 4.5) have led to divergent interpretations. Sample preparation and characterization in these studies is far more challenging than it is in the study of single DNA molecules in dilute solution. Similarly, the measurement of conductivity for single molecules presents formidable technical difficulties.

The studies summarized in this chapter provide an overview of our rapidly evolving knowledge of electron transfer and charge transport processes in DNA. The biological implications are clear. Both oxidative damage and repair of DNA can involve electron transport processes in which an electron or hole migrates over distances of up to 100 base pairs (several hundred Å). However, much remains to be learned about the efficiency and dynamics of these processes, both in single DNA molecules and DNA-based materials. Reducing the energy gap between a singlet acceptor and a DNA bridge could lead to increased rates and efficiencies of single-

step electron transfer processes at long distances. Improved methods for photo-injection of holes and electrons into DNA could result in more efficient long-distance transport processes. These and other advances could ultimately lead to the development of effective single molecule and nanostructured devices for molecular electronics.

Acknowledgments

The author wishes to express his gratitude to his colleagues and students. First, to Robert L. Letsinger for revealing the beauty of nucleic acid chemistry. Next, to Michael R. Wasielewski and his students for unraveling the complexities of electron transfer dynamics, to Mark Ratner for explaining the relationship of experiment and theory, and to Martin Egli and his students for solving the first hairpin structure—our “Rosetta Stone”. Finally to my students, especially to Taifeng Wu who got us off to a running start, to Yifan Zhang, Xiaoyang Liu, Yansheng Wu, and Jianqin Liu who have carried the torch, and to the indispensable Rajdeep Kalgutar. The author’s research on DNA electron transfer is supported by the Division of Chemical Sciences, Office of Basic Energy Sciences, U.S. Department of Energy.

Addendum

Since the preparation of this manuscript a number of significant papers related to the topic of this chapter have been published. Several of these merit special mention, including a concise overview of the topic by Grinstaff [1] and reviews of long distance charge transport by Schuster [2] and Giese [3] that summarize the seminal contributions of their laboratories. The crystal structure of a sequence-specific rhodium intercalator bound to an eight-base pair duplex has been determined with 1.2 Å resolution [4]. The occurrence of oxidative repair of thymine dimers in DNA via a long-distance hole-transport mechanism has been challenged by Dotse et al. [5]. However, further evidence in support of dimer repair has been advanced by McLaughlin, Barton and colleagues [6]. The effects of distance and base sequence upon hole transport between GGG and GG sequences has been investigated by Nakatani et al. [7] and Williams et al. [8], respectively, and the dynamics and equilibria for oxidation of G, GG, and GGG sequences have been studied in the author's laboratory [9].

Part 2

Artificial Supramolecular Systems

1 Covalently Linked Systems Based on Organic Components

Michael N. Paddon-Row

1.1 Introduction

Electron transfer (ET) is the most elementary and ubiquitous of all chemical reactions, playing a key role in many essential biological processes. There are three principal modes of energetically activating ET, namely thermal, optical, and photoinduced ET (Figure 1). Optical ET differs from photoinduced ET in that, for the former process, ET occurs during electronic excitation into a charge transfer (CT) or intervalence band, whereas for the latter process ET takes place after electronic excitation, from a locally excited state intermediate. Three important types of ET are charge separation, charge recombination, and charge shift (Figure 1), and these may be promoted either thermally, photochemically or optically.

A particularly significant type of ET is photoinduced charge separation between two bichromophores (or redox centres), as illustrated in Figure 2. The first step involves local excitation of either the Donor (**D**) or Acceptor (**A**) chromophore to generate the locally excited state, e.g., $^*\mathbf{D}-\mathbf{A}$. Exergonic charge separation (k_{cs}) competes with decay modes (k_d) leading to the ground state, to generate the charge-separated (CS) state, $^+\mathbf{D}-\mathbf{A}^-$. The importance of the photoinduced charge separation process lies in its transduction of light energy into useful chemical potential, measured by the free energy change, ΔG_{cr} , for charge recombination. Such CS states may therefore be regarded as molecular photovoltaic devices. A classic example of the usefulness of photoinduced charge separation in biology is the vital role it plays in the primary events of photosynthesis.

The successful design of both natural and artificial molecular photovoltaic devices rests on meeting three fundamental requirements, namely [1]:

- 1) The quantum yield for the charge separation process should be as high as possible. That is, $k_{cs} \gg k_d$ (Figure 2).
- 2) The lifetime, τ_{cr} ($= 1/k_{cr}$), of the CS state must be sufficiently long to enable it to carry out “useful” chemical work. In practice, it would be useful to aim for τ_{cr}

Figure 1. Three different types of electron transfer processes. Bottom box: Those chromophores bearing an asterisk (e.g., *C_1) indicate that they are in an electronically excited state, generated by absorption of light.

Figure 2. Energy diagram illustrating the possible pathways available in a photoinduced charge separation process between a donor (D) and an acceptor (A).

values lying in the microsecond domain, since this would allow diffusion controlled reactions involving the CS state to occur with 100 % efficiency, even in viscous solvents.

- 3) The energy content of the CS state should be as high as possible, thereby ensuring maximum conversion of photonic energy into chemical potential. Thus, $|\Delta G_{cs}|$ should be as small as practicable while ensuring that requirement (1) is met.

Meeting these design criteria requires a sound knowledge of the fundamental mechanisms of electron transfer processes. The theoretical framework for most ET reactions is based on a simple two-state model (Figure 3). The energy surface for an ET process, conveniently represented by a one-dimension reaction coordinate which is supposed to describe changes in both geometry of the D-A system and solvent orientation, may be regarded in terms of two diabatic surfaces, one representing the electronic configuration of the reactant, D-A, and the other representing the electronic configuration of the product, $^+D-A^-$. In the region where the diabatic surfaces intersect, the two configurations mix, symmetry permitting, and this results in an avoided crossing. The magnitude of the avoided crossing is given by $2V_{el}$, where V_{el} is the electronic coupling matrix element and may be regarded as a rough measure of the strength of orbital interactions between D and A.

In the case of long-range ET, where the donor and acceptor chromophores are separated by distances which exceed the sum of their van der Waals radii, V_{el} is

Figure 3. Energy diagram for charge separation resolved into reactant-like and product-like diabatic surfaces. The two diabatic curves do not intersect, but interact, to give an avoided crossing, whose energy gap is twice the electronic coupling, V_{el} , for the interaction.

generally very small ($<150\text{ cm}^{-1}$). ET then occurs nonadiabatically and the Fermi Golden Rule formalism of Eq. 1 may be used to express the ET rate constant, k_{et} :

$$k_{et} = \frac{4\pi^2}{h} |V_{el}|^2 FCWD \quad (1)$$

In this equation, *FCWD* is the Franck–Condon weighted density of states, and it contains information concerning overlap between the vibrational wavefunctions of the reactant and product states.

In the Marcus–Hush semiclassical treatment, Eq. 1 is simplified to Eq. 2 [2, 3]. In this expression, ΔG_{et} is the free energy change associated with the ET process and λ is the reorganization energy (Figure 3), and is approximately given by the sum of vibrational contributions from the donor and acceptor chromophores (internal reorganization energy, λ_i) and low-frequency contributions from the solvent (solvent reorganization energy, λ_s); \hbar and k_B are Planck’s constant and Boltzmann’s constant, respectively, and T is the temperature.

$$k_{et} = \frac{4\pi^2}{\hbar} |V_{el}|^2 \frac{1}{\sqrt{4\pi\lambda k_B T}} \exp\left(\frac{-\{\Delta G_{et} + \lambda\}^2}{4\lambda k_B T}\right) \quad (2)$$

Thus, within the context of Marcus–Hush theory, the three important variables that determine the ET rate constant are V_{el} , λ , and ΔG_{et} . It therefore follows that an understanding of ET processes entails an understanding of how these three variables are determined by factors such as the electronic properties of the donor and acceptor chromophores, the nature of the intervening medium, and interchromophore separation and orientation. The distance dependence of ET dynamics is a particularly important problem and, in order to investigate it experimentally, it is obviously advisable to employ donor–acceptor systems that are “rigid” in the sense that the donor and acceptor groups are held in well-defined distances and orientations with respect to each other.

It is possible to investigate the distance dependence of ET dynamics *intermolecularly* by dissolving the donor and acceptor chromophores in glasses. In these systems, the donor and acceptor groups are statistically distributed over a wide range of orientations and distances; nevertheless reasonable ET rate–distance profiles have been obtained from statistical analysis of the rate data [4, 5]. A more tractable method is to use systems in which the donor and acceptor groups are connected to each other, either by covalent linkages or by noncovalent interactions, such as H-bonds. The purpose of this chapter is to provide a brief overview of the important mechanistic insights into intramolecular ET processes using covalently linked multichromophoric systems. These systems will be denoted by **D–B–A** for a bichromophoric system (or dyad) in which the donor (**D**) and acceptor (**A**) groups are covalently attached to a bridge (**B**). This review will be restricted to organic chromophores, as opposed to transition metal complexes which are reviewed in Chapter 3 of this section of the handbook. Porphyrin-based chromophores will only be briefly mentioned, as they are treated in detail in Chapter 2 of this section.

Bridges that will be surveyed include saturated hydrocarbon bridges, unsaturated conjugated hydrocarbon bridges, and DNA. This review is not intended to be exhaustive, because many extensive reviews have already been published in this area [6–14].

1.2 The Superexchange Mechanism

There is another, compelling reason for studying intramolecular ET in covalently linked multichromophoric systems, and this involves the question of the influence of the intervening medium on ET dynamics. Clearly, the medium will influence ET dynamics by its effect on the driving force ($-\Delta G_{et}$) and the solvent reorganization energy terms in the Marcus–Hush expression. More subtly, the medium may even participate in the ET process by electronic coupling with the donor and acceptor chromophores. This interaction is manifested by a strengthening of the electronic coupling term, V_{el} .

Before considering more deeply, the question of the involvement of the medium on the electronic coupling between the donor and acceptor groups, it is instructive to examine the situation of ET taking place in vacuo. In the absence of any intervening medium between the redox couple, the electronic coupling depends on the direct, through-space (TS) overlap between the orbitals of the donor and acceptor groups that are primarily involved in the electron transfer process. Because orbital overlap decays exponentially with increasing interorbital separation, it is expected that the magnitude of TS electronic coupling should display similar decay characteristics [15]. Thus, both V_{el} and the associated ET rate constant, k_{et} , decay approximately exponentially with increasing interchromophore separation, r , according to Eqs. 3 and 4:

$$V_{el} \propto \exp(-0.5\beta_{el}r) \quad (3)$$

$$k_{et} \propto \exp(-\beta r) \quad (4)$$

where β_{el} and β are damping factors. It is often assumed that β_{el} and β have identical magnitudes, but this is not strictly correct because β , being a phenomenological quantity, incorporates distance dependence contributions, not only from V_{el} , but also from Franck–Condon factors, such as the solvent reorganization energy, λ_s . Thus, β is expected to be slightly larger than β_{el} , although it is often assumed that β_{el} and β have similar magnitudes.

The analysis of TS coupling may be quantified by calculating the coupling between two degenerate π -type orbitals placed in a vacuum as a function of interorbital separation (Figure 4). The orbital degeneracy is lifted by TS orbital overlap and gives rise to a splitting energy, $\Delta E(\pi)$. It is readily shown that $\Delta E(\pi)$ is twice the electronic coupling V_{el} for ET in the system (Figure 4) and a simple *ab initio* MO calculation predicts that $\beta_{el} \approx 3.0 \text{ \AA}^{-1}$ for TS coupling [15]. This is a very large

Through-space (TS) coupling:

Figure 4. Distance dependence of through-space interactions between two equivalent π -type orbitals. The value of β_{el} was obtained using the HF/3-21G theoretical model.

value for the damping factor, and it suggests that the ET rate is attenuated by a factor of 20 per angstrom increase in the interorbital separation. Consequently, long-range ET occurring through-space (i.e., in a vacuum) should be very slow for donor–acceptor separations exceeding 6 Å.

We now return to the question of whether an intervening nonconjugated medium could facilitate ET. Such a medium, which may comprise a saturated hydrocarbon bridge, a protein or oligopeptide, π -stacks, or even solvent molecules, could facilitate ET by what is known as a superexchange mechanism [16, 17]; to put it crudely, the medium provides “orbitals” ($\pi, \pi^*, \sigma, \sigma^*$, etc.) which the migrating electron can use to tunnel between the chromophores (Figure 5). In those situations where the medium is saturated and only σ and σ^* orbitals are available for coupling with the chromophores, the superexchange mechanism is then often referred to as a through-bond (TB) coupling mechanism [15, 18, 19].

Long-range ET mediated by the intervening medium

Figure 5. Long-range ET. Direct overlap between the donor and acceptor orbitals is negligible, and ET occurs by an indirect mechanism involving electron tunneling through the orbitals of the intervening medium, e.g., solvent molecules (upper) or a covalently linked saturated bridge (lower).

Figure 6. Schematic of the superexchange mechanism. In the region of the avoided crossing, virtual states resulting from ionization of the bridge are constructed, and these configurations are mixed into the reactant and product diabatic configurations to give the coupling, V_{el} . If virtual anionic bridge states, $^+D-B-A^-$, are more important than cationic bridge states, $D-B^+-A^-$, in the mixing scheme the process is often termed electron transfer. If the reverse holds, then it is termed hole transfer.

A more accurate representation of the superexchange mechanism is depicted in Figure 6 for the case of charge separation occurring in a $D-B-A$ dyad in which the bridge, B , consists of n subunits, B_i . Each subunit might, for example, be a two-center bond such as a C-C bond, or a larger entity, such as a benzene ring. The charge separation process may now be viewed as coupling of the reactant $D-B-A$ and product $^+D-B-A^-$ states with the two sets of virtual ionic bridge configurations $^+D-B_i^-A^-$ and $D-B_i^+-A^-$ ($i = 1, 2, \dots, n$). The first set of virtual configurations is generated by transferring the active electron from D into the various virtual orbitals of the bridge, whereas the second set of configurations is generated by transferring an electron from the various filled orbitals of the bridge to A .

It is important to note that, in the superexchange mechanism, these virtual ionic bridge configurations have no physical existence; they are not intermediates in the charge separation process since their energies are much higher than those of the reactant and product states. These virtual configurations generally only become significant in the region of the avoided crossing of the reactant and product diabatic

configurations on the potential energy surface for charge separation, whereupon they mix with the reactant and product configurations (Figure 6, lower section). This mixing results in an increase in the magnitude of the electronic coupling, V_{el} , over that resulting merely from direct, TS mixing of the reactant and product configurations alone. If the ${}^+\mathbf{D}-\mathbf{B}_i^--\mathbf{A}$ configurations mix more strongly with the reactant and product configurations at the avoided crossing than the $\mathbf{D}-\mathbf{B}_i^+-\mathbf{A}^-$ configurations, then the charge separation is said to occur by an electron transfer mechanism. This is because the mixing may be viewed in terms of an electron being propagated through the bridge. If, on the other hand, the $\mathbf{D}-\mathbf{B}_i^+-\mathbf{A}^-$ configurations mix more strongly with the reactant and product configurations than the ${}^+\mathbf{D}-\mathbf{B}_i^--\mathbf{A}$ configurations, then the charge separation is said to occur by a hole transfer (HT) mechanism, since the mixing may be loosely viewed as the propagation of a hole through the bridge.

A simple orbital description of the McConnell version of the superexchange, or TB mechanism [17] is given in Figure 7a for a system comprising two identical chromophores, \mathbf{C} , which are coupled through n identical bridge subunits, \mathbf{B}_i , each subunit contributing a single orbital to the coupling scheme. Within the McConnell treatment, only nearest-neighbor interactions are included and these are denoted by T , for the interaction between the chromophore \mathbf{C} and its nearest bridge subunit and by t , for the interaction between two adjacent bridge subunits.

The McConnell model may be exemplified by considering superexchange-mediated HT in a covalently linked dyad possessing a saturated hydrocarbon bridge (Figure 7b) [14]. In this case, the predominant coupling involves the bridge σ orbitals, rather than the σ^* orbitals, because the former are closer in energy to the donor

Figure 7. Orbital description of the superexchange (through-bond) mechanism. T is the interaction matrix element between the π orbital and the C–C σ orbital and t is the interaction matrix element between two *geminal* C–C σ orbitals.

level than are the latter [20]. Mixing of the (nearly) degenerate symmetry-adapted pair of π orbitals of the chromophores with the σ manifold of the bridge results in the lifting of the π orbital degeneracy by an amount $\Delta E(\pi)$ which, to second order, is given by [17]

$$\Delta E(\pi) = -2 \left(\frac{T^2}{\Delta} \right) \left(\frac{t}{\Delta} \right)^{n-1} \quad (5)$$

where Δ is the energy gap between the chromophore π orbitals and the bridge σ orbitals prior to their interaction with each other, and n is the number of σ orbitals (= number of bonds in the bridge). This is an intuitive result in that there is a T interaction for the coupling of each chromophore to the bridge and a t/Δ factor for each hop between adjacent bridge sites.

There are two important predictions of the McConnell model. Firstly, the splitting due to TB coupling falls off exponentially with the number of bonds in the relay. Equating Eq. 5 with Eq. 3 (bearing in mind that $\Delta E(\pi) = 2V_{el}$) gives:

$$\beta = 2 \ln \left| \frac{\Delta}{t} \right| \quad (6)$$

Secondly, the net splitting is given by a product of two terms, one giving the coupling of the chromophore to the bridge (T^2/Δ) and the other term, $(t/\Delta)^{n-1}$, giving the propagation of the interaction along the bridge.

It should be noted that there are a number of assumptions and approximations in the derivation of the McConnell equation. These include:

- 1) Restriction to nearest-neighbor interactions only.
- 2) Restriction to a single relay between the chromophores.
- 3) Restriction to only a single orbital on each site.
- 4) The assumption that all bridge sites are identical.
- 5) The assumption that the weak-coupling limit is valid (i.e., $|t/\Delta| \ll 1$ and $|T/\Delta| \ll 1$).

The assumption regarding the equivalence of the various bridge sites is readily relaxed, giving [21–23]

$$\Delta E(\pi) = \frac{-2T_{D,1}T_{n,A}}{\Delta_1} \prod_{i=1}^{n-1} \frac{t_{i,i+1}}{\Delta_{i+1}} \quad (7)$$

where $t_{i,i+1}$ is the coupling between the bridge sites i and $i+1$, $T_{D,1}$ and $T_{n,A}$ are the matrix elements giving the coupling of the chromophores to the ends of the bridge and $\Delta_i = \varepsilon - \varepsilon_i$ is the energy difference between the chromophore levels and the bridge level i . (The “D” and “A” denote “donor” and “acceptor” chromophores, respectively.)

In summary, both through-space and superexchange (or TB) mechanisms predict an exponential diminution of ET rate with distance, but that TB-mediated ET

should display a weaker distance dependence. The important question is, what is the distance dependence (i.e., β) of TB-mediated electron transfer dynamics, and how does the value of β depend on the nature, i.e., the electronic properties, of the bridge? This question may be profitably investigated experimentally using covalently linked **D–B–A** systems. The bridges in these systems, therefore, often serve the dual function of providing both a molecular scaffolding to which the chromophores are affixed at well-defined separations and orientations, and a medium which modulates the ET dynamics by the superexchange mechanism.

1.3 Experimental Investigations of the Superexchange Mechanism for ET Processes

Early studies of the distance dependence of ET dynamics focused on intramolecular electron-spin transfer in radical anions containing two equivalent π -moieties separated by a hydrocarbon bridge (Figure 8). One of these moieties, which houses the unpaired electron, functions as the donor, while the other (neutral) is an acceptor. ESR studies of the radical anions of α,ω -diarylethanes, **Ar**-(CH₂)_{*n*}-**Ar** **1**(*n*) and re-

Figure 8. Some covalently linked dyads for investigating thermal charge shift reactions in the radical anions.

lated systems, showed that electron transfer or, more accurately, spin transfer, was rapid on the hyperfine time-scale ($>10^7 \text{ s}^{-1}$) for $n = 1, 2$ but that it is slow for longer chains [24–27]. At the time, these results suggested that for the first two members of the series, **1(1)** and **1(2)**, the chains are short enough to permit ET to occur directly, through space, whereas for the higher members of the series, the chains, although flexible, permit only occasional “contact” between the two terminal aromatic moieties to take place. The possibility that ET in **1(1)** and **1(2)** was occurring through the alkane chain was investigated theoretically by McConnell [17]. Indeed, it was this study which led to the development of his famous superexchange equation, Eq. 5.

McConnell’s calculations led to the conclusion that TB-mediated electron transfer is fast for **1(1)** and **1(2)** but that it falls off exponentially with increasing chain length, by a factor of at least 10 for each additional CH_2 unit. This conclusion was based on the assumption that the ratio $|t/\Delta|$ for **1(*n*)** is about 0.25 (see Eq. 5). Interestingly, this estimate for $|t/\Delta|$ gives a β value of 2.8 \AA^{-1} (Eq. 6) which is comparable to that calculated recently for the TS mechanism [15]. McConnell’s calculations supported the experimental data at the time and they also suggested that the rate of TB-mediated ET should display a strong exponential decay with increasing donor–acceptor separation, becoming insignificant for alkane bridges containing more than two methylene groups. Thus, the observation of intramolecular ET in the series of dinaphthyl radical anions **2(*n*)** for values of n ranging from 3 to 20 was attributed to short-range, through-space ET, permitted by the flexible alkyl chain occasionally adopting appropriate conformations [28].

The belief (based on the McConnell 1961 paper [17]) that TB-mediated ET should be strongly damped with distance prevailed for quite some time, notwithstanding the clearly stated caveat in that paper that the numerical details should not be taken too seriously. It was this widespread belief which caused the conundrum over the observation of extremely rapid (10^7 s^{-1}) intramolecular ET in the radical anion of the semiflexible *trans*-dinaphthyl-cyclohexane system **3(7)** [29]. In the case of **3(7)** and the majority of other structure numbers, the number contained within parentheses refers to the number of C–C sigma bonds in the shortest chain (or relay or bridge) connecting the donor and acceptor chromophores. Thus, for **3(7)** the two naphthalene chromophores are connected by two relays, each of which contains seven C–C bonds. In a few other cases, e.g., **1(*n*)**, the number in parentheses refers to the number of repeating units in the chain (e.g., the number of CH_2 groups in the hydrocarbon chain of **1(*n*)**). The context within which the parenthetical number, corresponding to a particular molecular structure, is used, i.e., number of bonds versus number of repeating units, should become apparent upon inspection of the structural formula. For steric reasons, the cyclohexane ring in **3(7)** is forced to adopt the conformation as depicted; consequently, the two naphthalene rings are about 7 \AA apart (edge-to-edge). In spite of this very large interchromophore distance, the rapid ET rate was tacitly attributed to a TS mechanism, rather than to a TB mechanism occurring through two relays, each comprising seven saturated C–C bonds. A similar TS mechanism was advanced to account for the observation of rapid intramolecular ET in the anion radical of **4(6)** [27].

In contrast, kinetic studies of the dissolving metal reduction (Birch reduction) of

Figure 9. Metal–ammonia reductions of double bonds aided by a through-bond(TB)-mediated ET process from benzene radical anions.

the benzo-bridge-alkene systems, such as **6(3)** and **7(4)** were being interpreted in terms of a TB-mediated ET mechanism (Figure 9). It was found that the alkene double bonds in these systems were undergoing unusually rapid Birch reduction, which is quite out of character because nonconjugated double bonds are practically inert under Birch reduction conditions [30, 31]. For example, the double bond in **7(4)** is reduced some 2900 times more rapidly than the double bond in norbornene. The proposed mechanism involves electron capture by the benzene group followed by intramolecular endergonic ET to the double bond and subsequent protonation of the resulting radical anion of the alkene (Figure 9b). The total rigidity of the norbornylogous bridges prevented the two chromophores from making close contact. Consequently, a TB-mediated ET mechanism, occurring through three bonds in **6(3)** and through four bonds in **7(4)** was proposed [30, 31].

The advantages offered by the rigidity of the norbornylogous bridge was exploited in the ESR and ENDOR studies of ET in the radical anion of the 6-bond

dinaphtho system **5(6)** [32]. In solvents of high-cation-solvating power (e.g., HMPA) rapid ($>10^7 \text{ s}^{-1}$) intramolecular ET was observed. Considering that the two naphthalene groups in **5(6)** are held 7.4 Å apart, it seems inescapable that the rapid ET rate observed in the derived radical anion is due to a TB mechanism. Consequently, the results observed for the radical anions of **3(7)** and **4(6)** were re-interpreted in terms of a TB-mediated ET mechanism [32].

It is quite amazing that the ET rates are so rapid ($>10^7 \text{ s}^{-1}$) in the radical anions of **3–5**, considering that the free energy change, ΔG_{et} , for ET in these systems is zero; consequently, the free energy of activation for the reaction is at its maximum value (this follows from Eq. 2; the nominator in the exponent is equal to λ^2 for a self-exchange process and it is not reduced by the presence of an exergonic ΔG_{et} term).

Calcaterra, Closs and Miller observed rapid intramolecular ET in the radical anions **8–10** in which the chromophores are attached to a rigid steroid bridge (Figure 10) [33]. The edge-to-edge distance between the two chromophores in these molecules is about 11 Å, and they are separated by nine C–C bonds. The radical anions of **7–10** in 2-methyltetrahydrofuran at room temperature were generated by reaction with solvated electrons formed by pulse radiolysis. These studies differ from those discussed above in that the ET processes in **7–10** are exergonic, rather

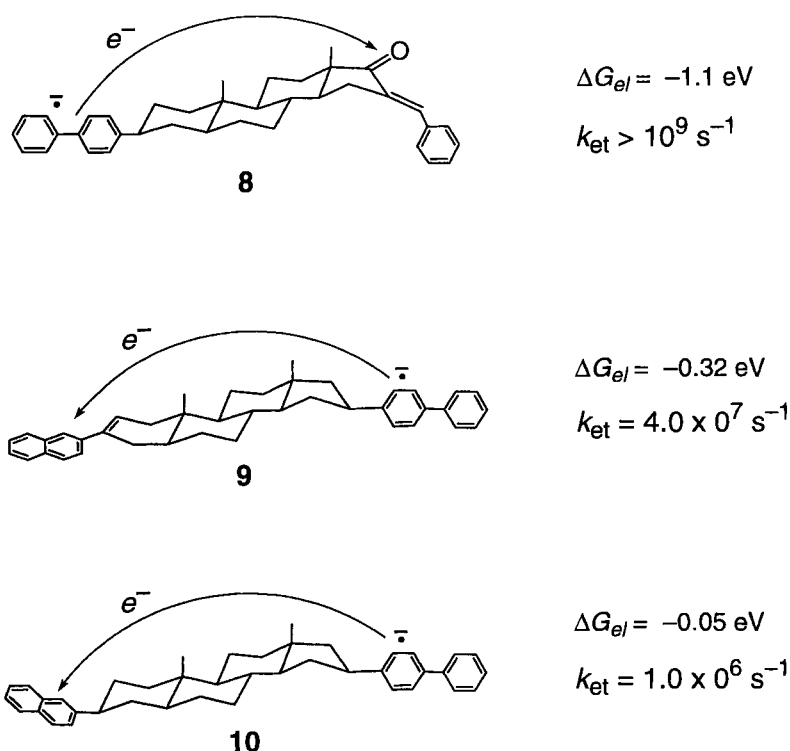

Figure 10. Charge shift reactions instigated by pulse radiolysis [33].

than self-exchange (the direction of ET is shown in Figure 10). The ET rate increases dramatically as the ET reaction becomes more exergonic. Considering the large “through-space” separation between the chromophores in these systems, it is extremely unlikely that the rapid ET is occurring by a TS mechanism. Thus, the steroid bridge must be mediating the ET by a TB coupling mechanism.

Intramolecular hole transfer has also been investigated [34, 35], a spectacular example being that observed using the 10-bond dyad **11(10)** [35]. In this system, the naphthalene (**Np**) and dimethoxynaphthalene (**DMN**) chromophores are rigidly separated, approximately 12 Å apart. Pulse radiolysis of a cyclohexane solution of **11(10)** at room temperature generated a statistical mixture of the two radical cations, $^+\text{Np-B-DMN}$ and Np-B-DMN^+ . Exergonic hole transfer from the **Np** radical cation to **DMN** in this mixture was found to occur on a subnanosecond time scale, thereby confirming that TB-mediated HT is extremely rapid, even over 10 bonds!

The anionic and cationic charge shift reactions discussed above all point to the conclusion that, contrary to earlier belief, superexchange-mediated ET reactions appear to be quite long-range processes, taking place on a (sub)nanosecond time scale over distances exceeding 10 Å. What is the distance dependence of the charge shift rates for these processes? Clearly, the β value must be much smaller than the earlier estimate [17] of c. 2.8 Å^{-1} , otherwise HT in the 4-bond analogue of **11(10)** would be predicted to occur within the unrealistically short time of 10^{-15} s , which is shorter than the period of a molecular vibration.

The first reliable determination of the distance dependence of the magnitude of the electronic coupling for charge shift reactions came from photoelectron spectroscopic (PES) and electron transmission spectroscopic (ETS) studies on the series of polynorbornane dienes **12(n)** (Figure 11) in conjunction with *ab initio* MO calculations. The dienes, **12(n)**, where n represents the number of C–C σ bonds along the side of the bridge, have played a pivotal role in the development of a detailed understanding of the role of TB interactions [14, 15, 18, 20, 36]. Figure 11 summarizes theoretical π -splittings and π^* -splittings ($\Delta E(\pi)$ and $\Delta E(\pi^*)$, respectively) for six molecules in the **12(n)** series, as well as experimentally determined π -ionization potential splittings, $\Delta IP(\pi)$, and π^* -electron affinity splittings, $\Delta EA(\pi^*)$ (from PES and ETS measurements, respectively) for the first two members of the series. The theoretical splittings were obtained from Hartree–Fock/3-21G calculations on the neutral molecules. Overall, excellent agreement is found between the calculated and measured splittings. This is remarkable since the calculations make use of the Koopmans’ theorem approximation [37] (i.e., they neglect orbital relaxation and electron correlation changes accompanying ionization or electron attachment) and employed the relatively modest 3-21G split-valence basis set [38]. Studies of other bichromophoric systems have revealed that splittings calculated using Koopmans’

Molecule	π Splittings (eV)		π^* Splittings (eV)	
	$\Delta IP(\pi)$	$\Delta E(\pi)$	$\Delta EA(\pi^*)$	$\Delta E(\pi^*)$
12(4)	0.87	1.02	0.80	0.91
12(6)	0.32	0.34	0.25	0.18
12(8)	—	0.15	—	0.088
12(10)	—	0.078	—	0.031
12(12)	—	0.04	—	0.010

Figure 11. Splittings for **12(*n*)** from ionization potentials, $\Delta IP(\pi)$, and electron affinities, $\Delta EA(\pi^*)$, together with HF/3-21G Koopmans' theorem splittings, $\Delta E(\pi)$, and $\Delta E(\pi^*)$.

theorem and using the 3-21G basis set are generally in good agreement with those obtained from calculations including relaxation and correlation effects and employing more flexible basis sets [36, 39]. The 3-21G basis set is insufficiently flexible for describing TS interactions occurring over distances exceeding 4 Å, and its success in calculating the net splittings in chromophore–bridge–chromophore systems with the chromophores separated by more than 4 Å is due to the domination of TB interactions.

The splittings in the **12(*n*)** series decay exponentially with increasing number of bridge σ -bonds:

$$\Delta E(\pi) = 5.89 \exp(-0.44n); \quad \beta_{el} = 0.88 \text{ bond}^{-1} \quad (8)$$

and

$$\Delta E(\pi^*) = 8.22 \exp(-0.60n); \quad \beta_{el} = 1.2 \text{ bond}^{-1} \quad (9)$$

where the β_{el} values were calculated using Eq. 3. The distance used in these equations is expressed using the number, n , of bonds which connect the two chromophores, rather than angstroms, since this number better represents the TB character of the interaction in these dienes.

The relevance of the PES and ETS studies to HT and ET processes is that the experimental $\Delta IP(\pi)$ splittings obtained for **12(4)** and **12(6)** are, to a good approximation, equal to twice the respective electronic coupling terms, V_{el} , for hole transfer in their radical cations (Figure 12). Likewise, the $\Delta EA(\pi^*)$ values obtained from the ETS measurements on these molecules are approximately equal to twice the respective electronic coupling terms, V_{el} , for electron transfer in their radical anions.

The origin of these relationships may be understood by considering, as an example, the potential energy surface for hole transfer in a diene radical cation, shown in

The vertical $\Delta IP(\pi)$ value for a symmetrical diene is proportional to V_{el} for hole transfer in the cation radical:

- $\Delta IP(\pi) = 2V_{el}$
- $\Delta E(\pi) = 2V_{el}$ (from Koopmans' theorem)

Figure 12. The relationship between the π ionization potential splitting energy in a diene and the electronic coupling element for hole transfer in the corresponding radical cation.

Figure 13. The two symmetry-adapted (through-space) combinations of π orbitals.

Figure 12. It is assumed that the neutral diene has C_{2v} symmetry. The diene radical cation has three π electrons and four π MOs, from which the two lowest energy configurations, namely $\pi_+^2\pi_-$ and $\pi_+\pi_-^2$, may be constructed, where the meaning of π_+ and π_- is explained in Figure 13. These two configurations may be represented simply by specifying the singly occupied π orbital in them, i.e., π_+ or π_- . Which of these two configurations is the ground state depends on the structure of the diene radical cation [15, 18, 40], and is not germane to this discussion.

The upper pair of potential energy curves in Figure 12 represents the adiabatic surfaces for the two π radical cations, e.g. π_+ and π_- . In the case of weak coupling between the two double bonds, the lower adiabatic surface has two minima, each of which corresponds to a distinct charge localized radical cation as indicated. In this case, the ground-state radical cation is nonsymmetrical, having the positive charge localized on one of the double bonds. Interconversion between the degenerate charge localized states takes place via the avoided crossing region which, presumably, has C_{2v} symmetry. In contrast, the higher electronically excited state surface (which would correspond, say to π_+) has a single energy minimum of C_{2v} symmetry. Thus, the charge is completely delocalized in this state, the three π electrons being evenly distributed over both double bonds.

The minimum of the ground-state potential energy hypersurface of the neutral diene lies directly below a point on the avoided crossing seam of the energy hypersurfaces of the two radical cation states that connects all points associated with C_{2v} symmetry. The transitions shown in Figure 12 represent the (Franck–Condon) vertical $IP(\pi)$ values for the formation of the π_+ and π_- radical cation states. The observed splitting energy, $\Delta IP(\pi)$, therefore provides a direct measure of $2V_{el}$ for hole transfer between the two radical cations. Similar reasoning may be used to demonstrate the connection between the experimental $\Delta EA(\pi^*)$ splits and V_{el} for electron transfer in the radical anions of the dienes.

It should be pointed out, however, that the true magnitude of V_{el} for hole transfer is not exactly equal to that determined by PE spectroscopy because the latter value corresponds to the energy difference between the cation states with geometries identical to that of the neutral diene, whereas the actual path for hole transfer will almost certainly traverse a different (and lower energy) region of the avoided crossing seam that is associated with a structure which is slightly different from that of the relaxed neutral species.

The good agreement between the experimental splits and the Koopmans' theorem calculated values suggests that the latter method offers a simple, yet approximate, way of calculating V_{el} for ET and HT processes in a variety of dyads. This proposal has been amply verified [23, 41–46].

Two important conclusions arise from the experimental and computational studies on **12**(*n*). Firstly, the $\Delta E(\pi)$ and $\Delta E(\pi^*)$ splittings for these dienes are large; even for the 12-bond diene, **12**(**12**), $\Delta E(\pi)$ and $\Delta E(\pi^*)$ are 0.04 and 0.01 eV, respectively, notwithstanding the 13.5 Å edge-to-edge distance between the two double bonds in this molecule [47]. Noting that a value of about 3 meV (24 cm⁻¹) for the electronic coupling element V_{el} is sufficient to promote rapid ET [2], the calculated V_{el} values of 20 and 5 meV for HT and ET, respectively, in **12**(**12**) suggest that TB-mediated ET and HT should be extremely rapid over very large distances indeed. These results are entirely in accord with the large experimental ET rates in **8**–**10** and for HT in the radical cation of **11**(**10**).

The second conclusion is the weak distance dependence of TB-mediated electronic coupling found for **12**(*n*), compared to that predicted on the basis of a TS mechanism. Thus, $\beta_{el} = 0.8$ and 1.2 bond⁻¹, for π and π^* coupling, respectively, in **12**(*n*), whereas $\beta_{el} = 3.0$ Å⁻¹ for a TS coupling mechanism. Why does the McConnell model predict a much stronger distance dependence behavior for TB-mediated electronic coupling ($\beta_{el} \approx 2.8$ Å⁻¹)? The main reason is the complete neglect of non-nearest-neighbor interactions in the McConnell model which, in fact, are quite large. This may be seen from the HF/3-21G calculated matrix elements for interactions between localized natural bond orbitals (NBOs) [48] in an alkane bridge (Figure 14) [45]. Although the matrix element between two adjacent C–C NBOs, t , is dominant, those which skip over one bond (t') and two bonds (t'') are by no means negligible. Indeed, inclusion of the t' matrix elements in a nonperturbative McConnell treatment of alkane dienes **13**(*n*) leads to a β_{el} value (0.88 bond⁻¹) which is much smaller than that obtained using the standard “nearest-neighbor” McConnell model (1.64 bond⁻¹), but which is still larger than the full Hartree–Fock value of 0.54 bond⁻¹. Upon inclusion of the t'' interactions, the β_{el} value becomes 0.58 bond⁻¹, very close to the Hartree–Fock result [45].

$$T = -1.13 \text{ eV} \quad t = -4.11 \text{ eV}$$

$$t' = 0.80 \text{ eV} \quad t'' = -0.29 \text{ eV}$$

Figure 14. HF/3-21G computed matrix elements for interactions between various natural bond orbitals (NBOs).

1.4 Examples of TS- and TB-Mediated Photoinduced ET Reactions

Investigations of photoinduced ET reactions in a wide range of covalently linked organic dyads are uncovering important mechanistic insights into charge separation processes. In particular, the photophysics of the dyads **14(n)** [49, 50], **15(n)** [51, 52], and **16(n)** [53–56] have been extensively studied. These systems, on account of the conformational flexibility of the polymethylene chains provide valuable information on the interplay between the dependence of photoinduced ET rates on chain conformation and the dynamics of the interconversion between various conformations of the chain. In these dyads, the aniline group (**An**) is the donor and the locally excited 9-anthracene group (**Anth**) in **14(n)** and **16(n)** and the locally excited 1-pyrenyl moiety (**Pyr**) in **15(n)** are the acceptor groups.

The overall photophysical processes which occur in these types of dyads are shown in Figure 15. Two sets of conformations may be identified in a dyad pos-

- 16(n)** a X = CN, Y = OMe, $n = 1 - 4$
 b X = CN, Y = H, $n = 1 - 4$

extended conformations

$$m = n - 2; \quad (n = \text{number of CH}_2 \text{ groups in the tether})$$

Figure 15. Schematic of photoinduced charge separation in a flexible tethered dyad. The extended and folded conformations are each intended to represent several similar conformations.

sessing a polymethylene chain comprising n CH_2 groups ($m = n - 2$), namely the extended set, in which the donor and acceptor groups are spatially well separated from each other by at least 4 \AA , and the folded set of conformations, in which the donor and acceptor groups may approach more closely to each other and are also able to adopt a face-to-face, sandwich-like disposition. The extended and folded sets are in dynamic equilibrium, although the population of the folded set of conformations diminishes with increasing chain length, on account of entropy factors.

Electronic excitation of either the donor or acceptor of the dyad generates two sets of locally excited states. In principle, the population of the folded set of excited states may be increased but in practice, this likelihood becomes negligible for long chain lengths ($n > 6$) since competing ET and decay processes occur more rapidly than the rate of production of a sandwich conformation from an extended one, which would require rotation about several C–C bonds to achieve.

The extended set of locally excited conformations will produce the charge-separated (CS) set of states, whereas the folded set will generate the exciplex state. Finally, Coulombic-induced molecular folding (harpooning [57]) in the extended set of CS states will lead to increased production of the exciplex state. The dynamic competition between the various processes outlined in Figure 15 depends not only on the chain length and the redox properties of the donor and acceptor groups, but also on solvent polarity.

Thus, for the three-carbon chain dyad **14(3)**, formation of both CS and exciplex states, ${}^-\text{Anth-B-An}^+$, was observed in the polar solvent acetonitrile. In contrast, in the nonpolar solvent 2-methylbutane, only formation of the exciplex state was observed [49, 50]. Presumably, in acetonitrile the CS state is stabilized by solvation

and so the driving force ($-\Delta G_{et}$; Figure 3) for its production is sufficiently high to permit its rapid formation (see Eq. 2). In 2-methylbutane, the driving force for production of the CS state is much weaker, and its rate of formation now becomes too slow to compete effectively with decay of the locally excited states of the extended set of conformations to the ground state.

The photophysics of the **Pyr-B-An** dyads **15**(*n*) also displayed interesting solvent-dependent behavior. In the case of **15**(1), photoinduced ET takes place readily in acetonitrile, to give the CS state, but it does not occur in nonpolar solvents—presumably because the driving force for formation of the CS is not very exergonic. Nevertheless, photoinduced ET is observed to take place for the three-atom chain dyad **15**(3) in polar and nonpolar solvents. In acetonitrile, the extended CS state is formed, whereas the exciplex is formed in *n*-hexane. In contrast to the shorter analogue **15**(1), the ideal, face-to-face sandwich-like orientation between the chromophores is attainable in the exciplex formed from **15**(3). Using the more viscous 2-propanol solvent allowed observation of the CS state, followed by slow formation of the exciplex. Apparently, the viscous solvent “slows” down the bond rotations that convert the CS state into the exciplex [51, 52].

Extensive photophysical studies have been carried out on the 9-anthryl-bridge-aniline dyad series **16**(*n*; X = CN; Y = H or OMe) [53–56]. For shorter members of these series (*n* < 5), rather predictable photoinduced ET behavior is assumed to occur; that is, following local excitation of the **Anth** acceptor, conformational changes in the bridge bring the two chromophores close enough for direct, through-space ET to take place. However, novel photophysical behavior was observed for the two-atom chain systems **16**(2a) and **16**(2b). In these dyads, TB coupling between the **Anth** acceptor LUMO and the **An** HOMO is believed to be strong enough to endow significant charge transfer to the ground state. This belief is supported by X-ray crystal structure data which reveal the conformation of **16**(2a) to possess near-optimal alignment of the **Anth** and **An** π -type orbitals for TB overlap with the central C–C bond of the ethane bridge, as depicted in Figure 16. These molecules may, therefore, be directly excited into the CS state. These experimental results provide additional support for photoinduced ET occurring by a TB-mediated mechanism [56].

There is ample evidence that the formation of excimers and exciplexes in covalently linked, α,ω -diarylalkanes is optimum for a chain length comprising three methylene groups, since this configuration allows a face-to-face sandwich-type structure to be achieved without imposing severe entropic penalties [58, 59]. A two-carbon atom chain is rather too short for optimal exciplex formation, but it facilitates TB mediated ET from an all-*trans* conformation, as shown in Figure 16b.

Investigations of charge transfer absorption bands in the series **17**(*n*) also reveal the importance of the TB coupling mechanism for a two-carbon atom bridge. A charge transfer absorption band, resulting from electron transfer from the dimethoxybenzene donor to the *N*-alkylpyridinium acceptor, was observed for the first two members of the series, **17**(*n*), *n* = 1, 2, but not for higher members, *n* = 3, 4. The comparatively intense CT band observed for **17**(2) was attributed to efficient TB-mediated charge transfer resulting from the molecule adopting the all-*trans* conformation, similar to that depicted for **16**(2a) in Figure 16b [60].

Figure 16. (a) Schematic of the X-ray structure of **16(2a)**, minus the CN and OMe substituents [56]. (b) Schematic showing the all-*trans* orbital overlap between the two chromophores and the central C–C bond of the bridge.

Charge transfer absorption and fluorescence bands were observed in **18(3)** and **19(5)** and related systems, the cause of which was explained in terms of TB interactions extending through three bonds, in the case of the former and through five bonds in the case of the latter [61, 62]. Confirmation of the operation of the TB mechanism in **19(5)** was obtained by the finding that the intensity of the CT absorption band for the *cis*-fused isomer, **20(5)** was more than five times weaker than that for the *trans*-fused isomer **19(5)** [62, 63]. Such behavior is to be expected of a TB mechanism whose strength is known to become progressively weaker with increasing numbers of *cis*-conformations in the chain [18, 19].

1.5 Distance Dependence of TB-Mediated ET in Saturated Hydrocarbon Bridges

The investigation of the distance dependence of ET dynamics using covalently linked dyads possessing flexible polymethylene chains has one advantage, but two potential serious disadvantages. The main advantage is ease of synthesis. The two disadvantages stem from the dynamic flexibility of the polymethylene chain. Firstly, for medium-length bridges there exist at any time conformations in which the donor and acceptor groups lie close enough to interact directly, through-space. The TB mechanism for ET in these systems will therefore compete unfavorably with the TS mechanism. Consequently, one might observe complicated distance dependence behavior for ET rates in such systems, changing from TB to TS for medium chain lengths and back to TB for long chain lengths. Nevertheless, clever strategies have been developed to circumvent this problem, and they will be discussed below. Secondly, it is known that the strength of TB coupling depends sensitively on the conformation of the sigma bonds in the bridge (*vide infra*) [18, 19]. Since polymethylene chains display a myriad of different conformations in solution, it follows that the ET rate obtained for any particular flexible-chain dyad will be averaged over all the possible conformations, making any interpretation in terms of TB coupling difficult.

Because of these considerations, most investigations of distance and orientation dependence of ET dynamics have been carried out using rigid bridges. It is also helpful if the **D–B–A** dyads possess symmetry. This facilitates the analysis of the electronic coupling between the chromophores and the bridge, as well as enabling one to explore the effect of orbital symmetry on ET dynamics.

As discussed above, the first study of the distance dependence of electronic coupling associated with ET and HT applied PES, ETS and Koopmans' theorem calculations to the rigid, symmetrical polynorbornane dienes **12(n)**, from which β_{el} values of 0.88 and 1.2 bond^{-1} were found for HT in the radical cations and ET in the radical anions, respectively. Although the electronic coupling could be calculated for a broad range of bridge lengths (up to 16 bonds), only the first two members of the series could be studied experimentally. It was clearly imperative to obtain an experimental determination of the distance dependence of ET rates based on more than two distances!

The breakthrough came with the design and successful synthesis of the dyads **23(n)** (Figure 17) [64]. These dyads, like the series **12(n)**, are based on the rigid norbornylogous bridge whose length ranges from four bonds (4.6 Å, edge-to-edge) to 13 bonds (14.2 Å). The **DMN** donor and dicyanovinyl (**DCV**) acceptor are well-suited for studying both photoinduced charge separation in the neutral systems and thermal charge shift ET in the derived anion radicals.

There are two points that should be borne in mind in the following discussion. Firstly, β values will generally be given in units of bond^{-1} , rather than in \AA^{-1} , because it seems more logical to do so when addressing the distance dependence of electronic coupling through bonds, rather than through space. The two units are simply related, however, by dividing the number of bonds in a particular bridge by

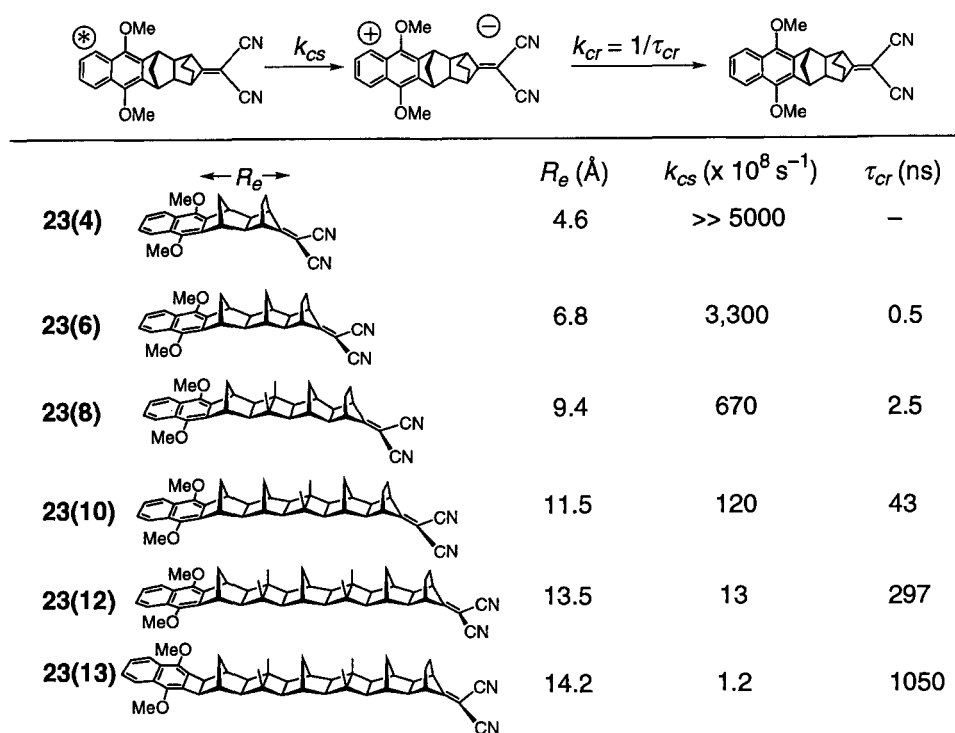

Figure 17. Rate data for photoinduced charge separation in the dyads **23(n)**. Charge separation rates, k_{cs} , were measured in THF and charge recombination lifetimes, τ_{cr} , in 1,4-dioxane [8, 66].

the edge-to-edge distance between the points of attachment of the chromophores to the bridge [47]. Secondly, as mentioned earlier, experimentally determined damping factors which have been derived from distance dependence behavior of ET rates and which have not been corrected for the distance dependence of Franck–Condon factors are denoted by β , whereas those damping factors which have been so corrected and refer, therefore, to the distance dependence of the electronic coupling element, V_{el} , are denoted by β_{el} .

Photoinduced charge separation in **23(n)** involves initial formation of the locally excited DMN chromophore and subsequent charge separation to form the CS state $^+\text{DMN-DCV}^-$ (Figure 18). The photoinduced charge separation rates, k_{cs} , for **23(n)** in THF were found to be extremely rapid, even for the 13-bond system (Figure 17), and they were fairly insensitive to solvent polarity, provided the charge separation process remained exergonic [65, 66]. For example, the photoinduced charge separation rate for **23(8)** increased by a factor of only 1.5, upon changing the solvent from cyclohexane (dielectric constant, $\epsilon_s = 2.02$) to acetonitrile ($\epsilon_s = 37.5$) [67].

That charge separation to form $^+\text{DMN-B-DCV}^-$ had actually occurred, following flash photolysis of the dyads **23(n)**, was unequivocally demonstrated using

Figure 18. A reaction schematic of the processes occurring following photon absorption by a dyad.

time-resolved microwave conductivity which provides a good estimate of the dipole moment, μ^* , of the product state [68]. The very large experimental values of μ^* for **22(n)** and their near-perfect agreement with the predicted values, μ , based on a point charge model (Figure 19) are entirely consistent with the formation of the giant dipolar states $^+\text{DMN-B-DCV}^-$ [8, 69, 70].

Having thereby established that we were indeed measuring rates of charge separation, the distance dependence of the ET dynamics in **23(n)** could be determined. Reasonable exponential fits were obtained for the charge separation rates as a function of the number of bridge bonds in various solvents. The phenomenological damping factor β was found to lie in the range [66]

$$\beta = 0.92 - 1.25 \text{ bond}^{-1}, \text{ or } 0.82 - 1.11 \text{ \AA}^{-1} \quad (10)$$

depending on the solvent. Presumably, the slight solvent dependence of β is due to the variation of the distance dependence of solvent reorganization energy with solvent.

This study, together with other experiments on **23(n)** (vide infra) provided the first definitive experimental evidence for the exponential distance dependence of long-range ET processes which was predicted on the basis of an exponential decay behavior of the electronic coupling element, V_{el} , with increasing donor–acceptor separation (Eq. 3).

The β values for photoinduced charge separation in **23(n)** (Eq. 10) are gratifyingly similar in magnitude to those predicted for hole transfer ($\beta_{el} = 0.88 \text{ bond}^{-1}$) and electron transfer ($\beta_{el} = 1.2 \text{ bond}^{-1}$) in the respective radical cations and anions of the dienes **12(n)** (vide supra), and lends strong support to the assertion that the extremely rapid rates of photoinduced ET observed in **23(n)** are the result of a superexchange mechanism mediated by the norbornylogous bridge.

An additional, elegant method of confirming the operation of TB-mediated ET in **23(n)** is to utilize one of the most important properties of TB interactions, namely the all-*trans* rule. This rule states that the magnitude of TB coupling depends on the configuration of the sigma-bridge and is maximized for an all-*trans* configuration

Figure 19. Dipole moments, μ^* , of the CS states of **23(n)** measured in benzene by time-resolved microwave conductivity (that for **23(4)** was measured in cyclohexane). The calculated values, μ , are based on a point charge model [8].

and becomes progressively weaker with an increasing number of *cis* or *gauche* “kinks” in the bridge (Figure 20a) [18, 19].

If the TB coupling mechanism were mediating the photoinduced ET processes observed for **23(n)**, then the rates of these processes should be modulated by changes in the configuration of the norbornylogous bridge, in accordance with the all-*trans* rule. This was tested using “kinked” systems, such as **24(8)** which possesses two *cisoid* arrangements of bridge bonds (Figure 20b). The photoinduced ET rate for the all-*trans* system **23(8)** was found to be faster than the “kinked” molecule **24(8)** by as much as an order of magnitude (Figure 20b), thereby confirming the operation of TB-mediated ET in the **23(n)**–**24(n)** series [71]. The modulation of ET dynamics by TB-mediated coupling in accordance with the all-*trans* rule has subsequently been used to interpret ET rate data for rigid, covalently linked systems containing porphyrin and quinone chromophores [72].

a The *all-trans* rule of TB coupling:**b** Experimental verification

Figure 20. (a) The *all-trans* rule of through-bond coupling; the magnitude of $\Delta E(\pi)$ decreases with increasing number of *cisoid* conformations in the bridge. (b) Ratio of the rates of photoinduced ET for **23(8)** and **24(8)** measured in acetonitrile [71].

It is amazing just how efficacious the TB mechanism can be in promoting ET. Thus, even for the 12-bond system, in which the DMN and DCV chromophores are 13.5 Å apart, photoinduced ET takes place on a nanosecond time scale with an efficiency approaching that found in the photosynthetic reaction center. Given the remarkable ability of the norbornylogous bridge and other saturated bridges [9] to promote ET over large distances, it is tempting to regard such bridges as molecular wires. However, it would be erroneous to do so, for reasons that will be given later.

The lifetimes, τ_{cr} , of the CS states, ${}^+\text{DMN-B-DCV}^-$ for direct charge recombination to the corresponding ground states markedly increase with increasing bridge length as, for example, revealed by the lifetime data for dioxane solvent (Figure 17). For a given bridge, τ_{cr} is significantly greater than the lifetime, τ_{cs} ($= 1/k_{cs}$) for charge separation, and this is mainly a consequence of the charge recombination reaction lying well into the Marcus inverted region [3, 73]. The driving force, $-\Delta G_{cs}$ for photoinduced charge separation in **23(n)** is about 1.0 eV in polar solvents, and is

almost as large as the estimated total reorganization energy for the process [66]. The charge separation reaction therefore occurs under near barrierless conditions (Eq. 2). In contrast, the driving force for the charge recombination process is substantially larger than the associated reorganization energy. Consequently, within the context of classical theory (Eq. 2), charge recombination in **23**(*n*) is associated with an activation barrier and this will slow it down, compared to the charge separation reaction.

The charge recombination rates for **23**(*n*) followed exponential decays with β values lying in the range [8, 35, 70]

$$\beta = 0.86 - 1.11 \text{ bond}^{-1}, \text{ or } 0.77 - 0.99 \text{ \AA}^{-1} \quad (11)$$

These values are similar, but slightly smaller than those observed for the charge separation reaction (Eq. 10). Clearly, the charge recombination process is also taking place by a TB-mediated mechanism in these dyads.

This study of charge recombination in the CS states of **23**(*n*) represented the first systematic measurement of the distance dependence of ET rates in the Marcus inverted region. The key conclusion from this study was the finding that the distance dependence of ET rates in the Marcus inverted region is similar to that in the normal region; that is, the β values are similar (cf. Eqs. 10 and 11).

The distance dependence behavior of the charge recombination (CR) rates for **23**(*n*) was found to be somewhat idiosyncratic in low-polarity solvents. Whereas a good exponential decay was found for the CR rates for all members of the series **23**(*n*) in dioxane (Figures 17 and 21), the CR rate reached a plateau and actually decreased for $n > 6$ in alkanes and for $n > 10$ in benzene (Figure 21).

The explanation for this phenomenon is the establishment of an extra decay channel for charge recombination; in addition to the normal CR process, k_{cr} , (upper right box of Figure 21) leading directly to the ground state, competing back electron transfer (BET) occurs to give the locally excited state, $^*\text{D-B-DCV}^-$ (k_{bet}) for the longer systems in nonpolar solvents. The locally excited state either decays to the ground state (k_d) or returns to the CS state (k_{cs}). The observation of delayed fluorescence for the $n > 6$ compounds in alkane solvents confirmed this mechanism [74]. This BET dominates the overall normal decay kinetics of the CS state for longer members of the series **23**(*n*) in nonpolar solvents because of the gradual increase in the level of the CS states resulting from the diminishing energy of Coulombic attraction between the charged centers, as shown for benzene solvent in Figure 22. The lifetimes of the CS states of **23**(*n*) for $n = 4$ –10, increase exponentially with increasing n , and no BET occurs because these states lie energetically too far below that of the locally excited state to be of importance. However, the CS state of **23**(12) is almost isoenergetic with $^*\text{DMN-B-DCV}$, and the dominant decay mode is BET followed by delayed fluorescence [70, 74]. Incidentally, the observation of the onset of delayed fluorescence in a system by altering the solvent polarity reveals the energy of the CS state since it must be very close to the energy of the locally excited state which may be easily and accurately determined.

Fluorescence spectra of the dyads **23**(*n*) revealed the presence of discrete charge transfer emission bands for bridge lengths up to 10 sigma bonds [75]. These bands

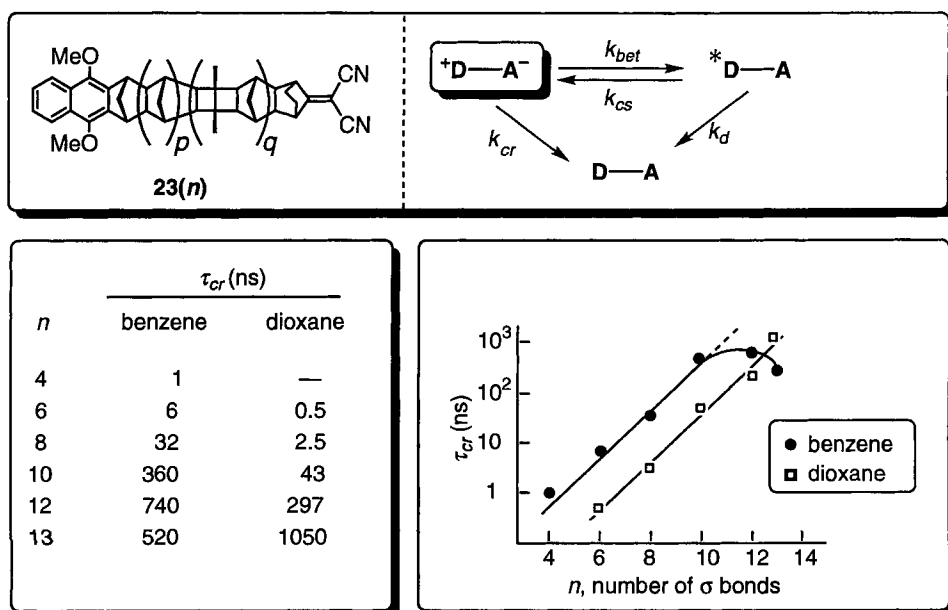

Figure 21. Dependence of the lifetime of the CS state of **23(n)** on the number of intervening σ bonds for benzene and dioxane solvents. The straight lines drawn through the data (extended as a dashed line for benzene) correspond to an exponential dependence of the charge recombination lifetime, τ_{cr} on n [74]. Note that the experimentally determined charge recombination lifetime, τ_{cr} , is *not* necessarily equal to $1/k_{cr}$, because it also includes a contribution from the lifetime of the BET process ($1/k_{bet}$).

enable the calculation of the electronic coupling element, V_{el} for charge recombination from the CS state to the ground state, since the radiative transition probability is related to V_{el} . The magnitude of V_{el} for the CR process in *n*-butylether (Figure 23) was found to decrease exponentially with increasing number of intervening bonds, from 370 cm^{-1} for **23(4)** to 17.6 cm^{-1} for **23(10)**. The damping factor, β_{el} for the decay of the electronic coupling element is

$$\beta_{el} = 1.02 \text{ bond}^{-1}, \text{ or } 0.91 \text{ \AA}^{-1} \quad (12)$$

which is remarkably similar to the β values found for charge separation and charge recombination, viz. Eqs. 10 and 11. Furthermore, the CR rate for **23(n)** was found to be proportional to $|V_{el}|^2$, thus providing experimental verification of the golden rule relationship, Eq. 1 [75].

Thermal charge shift intramolecular ET in the radical anions of **23(n)** (Figure 24a) using pulse radiolysis was found to be very rapid, $>10^9 \text{ s}^{-1}$ for all molecules [76]. Although direct measurements of the ET rate constants could not be obtained, optical electron transfer bands were observed in the visible–near–infrared absorp-

Figure 22. An ergodynamic representation of the changes occurring in the energy level of the CS states of **23(n)** as the number, n , of intervening σ bonds increases in a nonpolar solvent, together with the resulting changes in the ET kinetics between the CS state and the locally excited donor and ground states shown on the extreme left. The diagram shows how indirect charge recombination, by back ET, to regenerate the locally excited donor can eventually dominate the overall decay kinetics for long distances due to diminishing energy of Coulombic attraction between the charged centers. The lifetimes shown were measured in benzene solvent and are given in ns [74].

tion spectra of the radical anions of **23(4)**, **23(8)**, and **3(8)** (Figure 24b). These bands corresponded to optically induced ET from the DCV^- radical anion to **DMN** (Figure 24a). Analysis of these bands using Hush theory [77, 78] led to estimates of the magnitude of the electronic coupling V_{el} for the charge shift reaction (Figure 24c). These limited data give a β_{el} value of:

$$\beta_{el} = 0.84 \text{ bond}^{-1}, \text{ or } 0.75 \text{ \AA}^{-1} \quad (13)$$

The large values of V_{el} imply that the thermal charge shift ET reactions in the radical anions of **23(n)** are actually occurring adiabatically rather than non-adiabatically.

It is interesting to note that the electronic coupling elements, V_{el} are much larger for the charge shift ET reactions in the anion radicals of **23(n)** (Figure 24c) than for CR in the CS states in the respective systems (Figure 23), notwithstanding the comparable β_{el} values for the two reactions. For example, for **23(8)**, V_{el} is six times

Figure 23. Values of the electronic coupling elements, V_{el} , calculated from charge transfer fluorescence data for **23**(n) in *n*-butylether [75].

larger for charge shift ET than for CR. This difference in the V_{el} values is not surprising, considering that different active orbitals are involved in the two reactions.

The final investigation of the distance dependence of ET dynamics in norbornyl-ogous bridged systems involved photoinduced charge shift ET in **25**(4) and **25**(6) which possess the *N*-methylpyridinium acceptor (Figure 25) [79]. Local excitation of the DMN donor results in charge shift to form the distonic radical cation, e.g., **26**(4) from **25**(4). From the ET rates for the two dyads, an approximate damping factor of

$$\beta = 0.88 \text{ bond}^{-1}, \text{ or } 0.77 \text{ \AA}^{-1} \quad (14)$$

was obtained.

Summarizing the results for **23**(n)–**25**(n), the experimentally determined β values for different types of ET reactions (e.g., photoinduced charge separation, thermal charge shift ET, optical ET, etc.) having different driving forces, and occurring in both the Marcus normal and inverted regions, all lie within the rather narrow range of

$$\beta \approx 0.84 - 1.2 \text{ bond}^{-1} \quad (15)$$

(Eqs. 10–14) with the majority lying within 0.85 – 0.95 bond^{-1} . The near-constancy of β in these studies strongly indicates that its value reflects the distance dependence of the magnitude of TB coupling in the norbornyl-ogous bridge, a conclusion which receives support from the PES, ETS, and computational studies on **12**(n) (Eqs. 8 and 9). Thus, these results point to the overwhelming conclusion that TB-mediated ET occurs in **23**(n)–**25**(n) with a β value of c. 0.9 bond^{-1} .

Does the magnitude of β depend on the type of hydrocarbon bridge? Several important studies have provided an answer to this question. Through-bond coupling

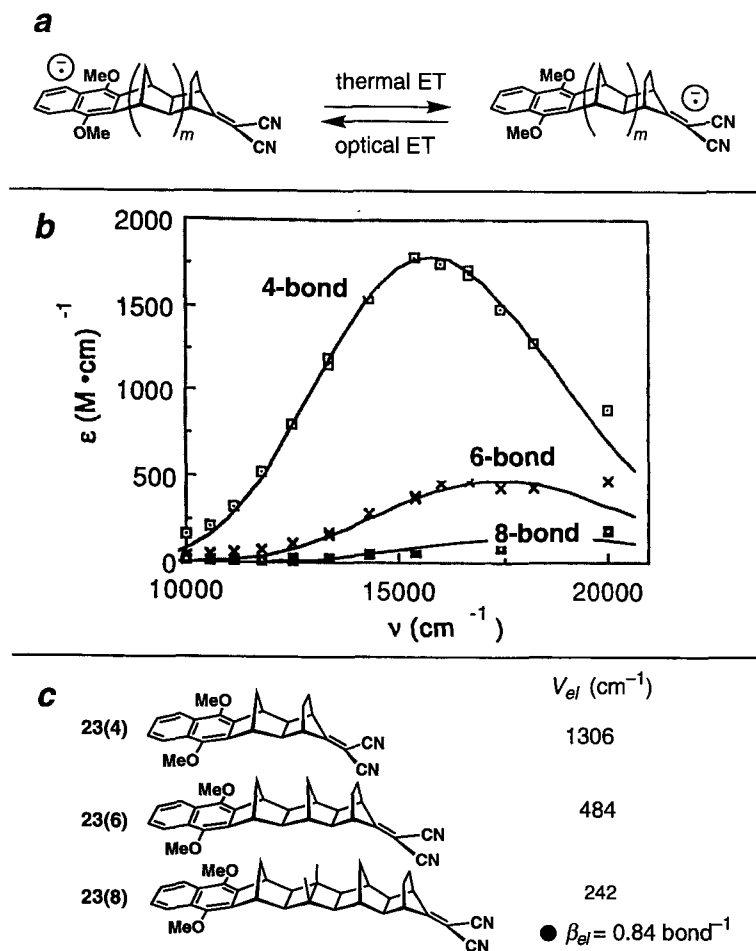

Figure 24. (a) Thermal ET occurs exergonically from DMN to DCV. Optical ET occurs in the opposite direction. (b) Optical electron transfer bands for the radical anions of **23**(*n*) in THF. (c) Values of the electronic coupling elements, V_{el} , were calculated from these bands using the following estimates of the reorganization energies: internal reorganization energy $\lambda_i = 0.55$ eV for all three dyads, and solvent reorganization energy $\lambda_s = 0.47$, 0.66 and 0.79 eV for **23**(4), **23**(6) and **23**(8), respectively [76].

in fused cyclohexane bridges has been investigated by Closs, Miller and colleagues [9, 34, 80]. This group measured thermal intramolecular charge shift ET rates in radical anions generated by pulse radiolysis, representative of which are **27**–**30** and **10**(**10**), in which the naphthalene acceptor and biphenyl radical anion donor are separated by 4–7 and 10 bonds, respectively (Figure 26; the through-bond count (in parentheses) is determined using the shortest path connecting the two chromophores). The distance dependence of the measured ET rates gave a poor fit to an

$$\beta = 0.90 \text{ bond}^{-1}, \text{ or } 0.80 \text{ \AA}^{-1} \quad (16)$$

Photoinduced ET in the dyads **31**(*n*), possessing porphyrin and quinone chromophores covalently linked to an oligo-bicyclo[2.2.2]octane bridge was investigated on the grounds that these systems were useful mimics of the photosynthetic reaction centre and that, therefore, the distance dependence of ET rates in **31**(*n*) should provide useful mechanistic information for interpreting the ET dynamics taking place in the photosynthetic reaction center [81–83]. The distance dependence of the ET rate, from the locally excited porphyrin donor to the quinone acceptor, gave a β value of:

$$\beta = 1.4 \text{ bond}^{-1}, \text{ or } 1.2 \text{ \AA}^{-1} \quad (17)$$

This is a larger value than those reported from other studies (Eqs. 10–16), and may reflect a significant contribution from the distance dependence of the Franck–Condon factor in the form of the solvent reorganization energy term. This is certainly plausible since the rate data were determined in a polar solvent (butyronitrile) and the solvent reorganization energy increases with increasing solvent polarity.

Electron transfer mediated by an oligo-spirocyclobutane bridge has been studied in two systems, **32**(*n*) and **33**(*n*). Photoinduced charge separation in **32**(*n*) is asso-

31(*n*) $n = 4m + 1$ ($m = 0, 1, 2$)

32(*n*) $n = 2m + 6$ ($m = 0, 1, 2, 3$)

33(*n*) $n = 2m + 4$ ($m = 0, 1, 2$)

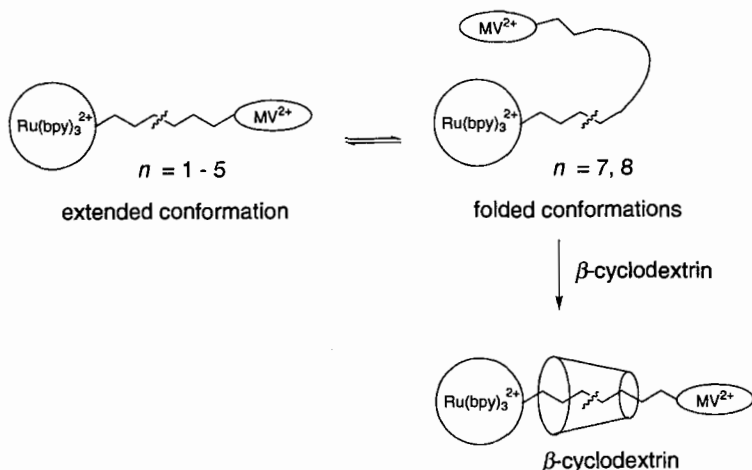

Figure 27. Polymethylene-linked dyads. For longer members of the series, β -cyclodextrin was added to ensure the chain was kept in the extended conformation [86].

ciated with a β value of [84]:

$$\beta = 1.03 \text{ bond}^{-1}, \text{ or } 0.92 \text{ \AA}^{-1} \quad (18)$$

The mixed-valence complexes **33(n)** displayed intervalence absorption bands from which the electronic coupling elements, V_{el} were calculated using Hush theory [77, 78]. The distance dependence of V_{el} was found to be [85]:

$$\beta = 0.88 \text{ bond}^{-1}, \text{ or } 0.78 \text{ \AA}^{-1} \quad (19)$$

Recent studies have shed light on the distance dependence of the rates of ET reactions proceeding through polymethylene chains. The rates of photoinduced forward and thermal charge recombination ET in the series of dyads **34(n)** (Figure 27) have been measured for various chain lengths, $n = 1-5, 7$, and 8 [86].

The rate of photoinduced ET, from the locally excited MLCT state of the Ru(bpy)_3^{2+} donor to the viologen acceptor in acetonitrile was found to decay exponentially with increasing chain length, from $n = 1-5$ and becomes roughly constant for $n = 5, 7$, and 8 . These results were interpreted in terms of TB-mediated ET

for dyads with short chain lengths ($n < 6$), for which the dyads exist predominantly in the extended conformation.

For longer chain lengths ($n > 6$), a through-solvent mechanism for ET was proposed and was assumed to occur in the various folded conformations of the dyads which are present in the longer chain systems (Figure 27). Support for this conjecture was obtained by encapsulation of the polymethylene chain by β -cyclodextrin which has the effect of “straightening” out the folded conformations (Figure 27). The photoinduced ET rates for the $n = 7, 8$ dyads determined in the presence of β -cyclodextrin now obeyed the same exponential decay with increasing chain length as the shorter chain members. Approximate values for the electronic coupling element were calculated from the rate data and estimates of the solvent reorganization energy. The distance dependence of V_{el} was found to be:

$$\beta_{el} = 1.32 \text{ bond}^{-1}, \text{ or } 1.18 \text{ \AA}^{-1} \quad (20)$$

The distance dependence for the reverse process, thermal charge recombination back to the ground state of **34**(n), which occurs in the Marcus inverted region, was also determined and was found to be similar to that for the forward photoinduced ET reaction:

$$\beta_{el} = 1.18 \text{ bond}^{-1}, \text{ or } 1.06 \text{ \AA}^{-1} \quad (21)$$

A similar study has been carried out on the series of polymethylene dyads **35**(n) and **36**(n) in which $n = 3\text{--}12$ [87]. The rate data fitted an exponential decay with increasing values of n , provided that the experiments were carried out in the presence of β -cyclodextrin for dyads with $n > 7$ (vide supra). The damping factor was calculated to be:

$$\beta_{el} = 1.09 \text{ bond}^{-1}, \text{ or } 0.97 \text{ \AA}^{-1} \quad (22)$$

In summary, the experimentally determined β values listed above in Eqs. 10–22 are, with two exceptions (Eqs. 17 and 20), reasonably constant, which is remark-

able, considering they have been measured for several different kinds of saturated hydrocarbon bridges, using various ET and HT processes occurring in both the Marcus normal and inverted regions. From these data, the average value of β for superexchange-mediated ET in saturated hydrocarbon bridges is:

$$\beta_{av} = 0.95 \pm 0.10 \text{ bond}^{-1} \quad (23)$$

This value, which contains a contribution from the distance dependence of the Franck–Condon factor, as well as that from electronic coupling, is only a rough indicator of the effectiveness of electronic coupling through saturated hydrocarbon bridges.

The approximate constancy of β for saturated hydrocarbon bridges does not imply similar magnitudes for V_{el} for different bridges of the same length, however. Consider, for example, the V_{el} values for charge recombination in the CS states of **23(n)** (Figure 23) and the charge shift reaction in the radical anions of the same series of dyads (Figure 24). For a given bridge length, the magnitude of V_{el} is between three and six times larger for the charge shift process than for the CR reaction. This difference is qualitatively understandable from a consideration of the simple McConnell model (Eq. 5); the magnitude of the electronic coupling depends on the ratio (T/Δ) and the magnitude of this ratio depends on the electronic properties of the donor and the type of active orbital involved in the ET or HT process (i.e., HOMO (highest occupied molecular orbital) or LUMO (lowest unoccupied molecular orbital)). For the CR process (Figure 23), the DMN HOMO is the active donor orbital, whereas for the charge shift reaction the DMN LUMO is the active donor orbital. Since the DMN HOMO and LUMO have different magnitudes of atomic orbital coefficients and they are also associated with different values of Δ , it follows that (T/Δ) will have different values for the two ET processes.

The McConnell expression (Eq. 5) also explains the relative insensitivity of β to the type of ET or HT process and to variation in redox properties of the chromophores. The distance dependence, β , of the electronic coupling is, within the weak coupling approximation implied by Eq. 5, governed by the ratio $|\Delta/t|$ in Eq. 6. The sensitivity of β to variation in the magnitude of Δ is given by Eq. 24:

$$\frac{\partial \beta}{\partial \Delta} = \frac{2}{\Delta} \quad (24)$$

For saturated hydrocarbon bridges, the energy gap, Δ between the π and π^* manifolds of the chromophores and the respective σ and σ^* manifolds of the bridge is large, of the order of several eV. Consequently, the term given on the right-hand side of Eq. 24 is small and so, therefore, will be the variation of β with Δ . However, this analysis is crude because of the neglect of non-nearest-neighbor interactions in the McConnell model. In the following two sections, it will be seen that the magnitudes of both β_{el} and V_{el} may, in fact, be modulated by the structure of the saturated hydrocarbon bridge as a result of interference effects.

1.6 A Simple Model for Dissecting TB Coupling in Bridges

The excellent agreement between the HF/3-21G Koopmans' theorem calculations of the $\Delta E(\pi)$ and $\Delta E(\pi^*)$ splitting energies with those determined experimentally (see Figure 11) offers a simple computational method for estimating the magnitude of the electronic coupling element for HT and ET in a variety of systems [14]. Notwithstanding this success, there is a need for gaining insight into which specific interactions are responsible for the couplings, and how they depend on the structure of the bridge. Several elegant treatments are available which provide such insight [14, 21–23, 36, 39, 42–45, 88–101]. Herein, a method, originally developed by Heilbronner and Schmelzer [40] is described which relies on the adoption of a localized orbital representation.

The groups of Paddon-Row, Jordan and coworkers [14, 36, 45, 96–101], Newton and coworkers [23, 43, 44] and Miller and coworkers [42, 92–94] have made use of the natural bond orbitals (NBOs) of Weinhold and coworkers [48]. These are a set of orthogonalized localized orbitals that conform closely to chemists' intuitive orbitals (core, two-center bonding and antibonding, lone pair, and Rydberg orbitals).

In general, Hartree–Fock calculations on molecules give molecular orbitals (MOs) that extend (i.e., are delocalized) over the entire molecular framework. These so-called canonical MOs (CMOs) may be transformed into localized orbitals, such as NBOs. Technically, the Fock matrix in the basis of CMOs (F^{CMO}) is converted into a Fock matrix in the basis of NBOs (F^{NBO}). The diagonal elements of F^{NBO} correspond to self-energies of the localized orbitals, and the off-diagonal matrix elements give the interactions between localized orbitals. Diagonalization of the full F^{NBO} matrix gives back the canonical MOs and eigenvalues. The major advantage of localized orbital approaches comes from the ability to construct Fock matrices retaining only a subset of the interactions. In essence, this allows one to construct a series of model one-electron Hamiltonians, with all matrix elements being derived from *ab initio* calculations. Examination of the splittings obtained from diagonalization of these modified Fock matrices provides information on the importance of specific interactions for the electronic couplings.

Figure 28 illustrates the application of the NBO analysis method to a simple four-orbital model, consisting of two *p* orbitals (p_1 and p_4) and the σ (σ_2) and σ^* (σ_3^*) of the intervening C–C bond. The diagonal entries of the NBO Fock matrix give the energies of the p_1, p_4, σ_2 , and σ_3^* localized orbitals in the absence of mixing with other localized orbitals. Firstly, the $\langle p_1 | F | p_4 \rangle$ off-diagonal matrix element is “switched on”. Diagonalization of the resulting 2×2 sub-matrix gives the delocalized orbitals $p_+ = (p_1 + p_2)$ and $p_- = (p_1 - p_2)$, and the resulting splitting provides a measure of the TS interaction. In the next step, mixing with σ_2 is included and this causes p_+ to be “pushed above” p_- , leading to the so-called inverted sequence of orbital ordering [40]. (By symmetry, p_- cannot mix with σ_2 .) Finally, switching on the interaction with σ_3^* results in a small stabilization of p_- . This analysis shows how NBOs can be used to separate the TS and TB interactions, and also how they can be used to estimate the relative importance of different TB coupling pathways.

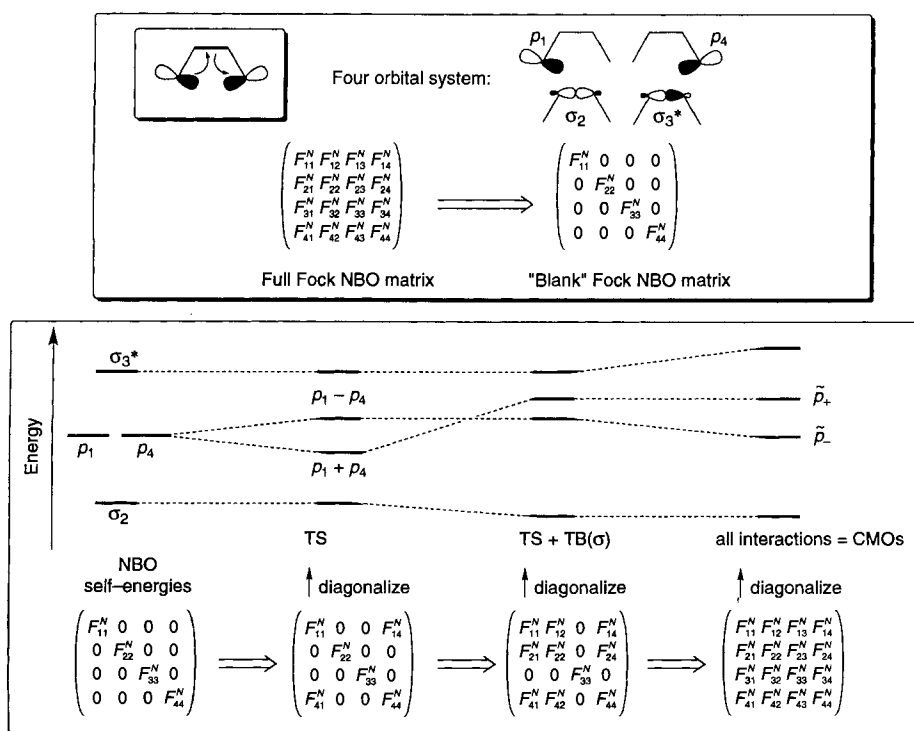

Figure 28. Illustration of the use of the NBO procedure for analyzing TB and TS interactions. The model includes two chromophore p orbitals and the σ and σ^* orbitals of the central C–C σ bond of the bridge. In the bottom part of the figure, the Fock matrix is built up, starting with the matrix of self-energies by adding, in succession, the TS coupling between p_1 and p_4 , the TB mixing with σ_2 , and, finally, the TB mixing with σ_2^* .

1.7 Interference Effects in TB Coupling

Figure 29 summarizes the β_{el} values obtained from the π_+ , π_- splittings for six ethylene–bridge–ethylene systems, **37**(n)–**41**(n) and **12**(n), differing in the type of hydrocarbon bridge. The π_+ , π_- splittings calculated for these molecules range from 0.017 to 0.058 eV, and the β_{el} values range from 0.50 to 2.48 bond^{−1}. The largest splitting and the smallest β_{el} value occur for the simple all-*trans* alkane bridge diene, **41**(n), and the smallest splittings and largest β_{el} value are for the molecules **37**(n) and **38**(n) with the fused cyclobutane bridge units. These results are surprising, since one would have expected bridges with multiple linkages between the π orbitals to be more effective at TB coupling than the “single strand” all-*trans*-(CH₂) _{n} bridge. This suggests that in the systems with bridges comprising hydrocarbon ring units, there must be considerable destructive interference between different TB coupling pathways, with the importance of destructive interference depending on the structure of the bridge units [91, 102].

	β_{el} (bond ⁻¹)	Example	$\Delta E(\pi)$ (eV)
37(<i>n</i>) 	2.48	 8σ	0.017
38(<i>n</i>) 	1.22	 10σ	0.025
12(<i>n</i>) 	0.68	 12σ	0.043
39(<i>n</i>) 	0.60	 13σ	0.038
40(<i>n</i>) 	0.58	 12σ	0.035
41(<i>n</i>) 	0.50	 12σ	0.058

Figure 29. Limiting β_{el} values for the π_+, π_- splittings in six ethylene-bridge-ethylene systems. These are obtained by fitting the HF/3-21G π_+, π_- splittings for consecutive members of the series to $\Delta E(\pi) = A \exp(-\beta_{el}n)$, where n equals the number of bonds along one side of the bridge.

The NBO procedure may be used to construct models that allow one to identify the major sources of destructive interference, and this is illustrated using the polynorbornane **12**(*n*) series. Each model retains the localized π orbitals on the ethylenic groups as well as a subset of the NBOs associated with the bridge. HF/3-21G calculations are carried out on the **12**(*n*), $n = 4, 6, 8, 10$, and 12 , molecules, and the canonical MOs are transformed to NBOs, which are used to construct a series of models shown in Figure 30. In terms of increasing sophistication these models are:

- A:** Only a single relay of C–C σ bonds is retained.
- B:** The two main relays of C–C σ bonds are retained, but no interactions between the relays are permitted.
- C:** Same as **B**, except that interactions between the two main relays (cross-talk) are permitted. The cross-talk interactions are symbolized by wavy lines.

These three models ignore interactions involving the C–H bonds, the bridging methylene groups, and the C–C bonds shared by fused rings. This approximation is justified since more complete NBO calculations in which such interactions are included lead to the same qualitative conclusions. The π_+, π_- splittings for the $n = 8, 10$, and 12 members of these models as well as the associated β_{el} values are sum-

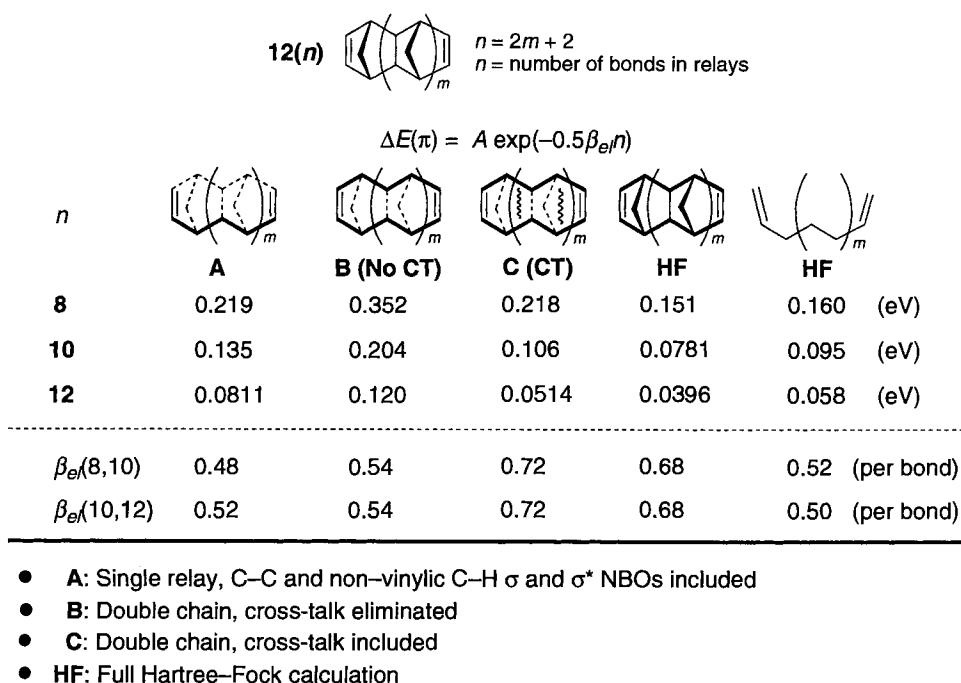

Figure 30. Analysis of cross-talk interactions in **12(*n*)**. Splitting energies are in eV. Three models, constructed from NBO/3-21G matrix elements for **12(8)**, **12(10)**, and **12(12)** are considered: model **A** allows for coupling through a single relay; model **B** through two relays, but with no cross-talk; and model **C** through two relays with cross-talk (represented by wavy lines). Results from Hartree–Fock calculations on the **12(*n*)** series as well as for the corresponding molecules with all-*trans* alkane bridges **41(*n*)** are also included.

marized in Figure 30. Also included are the Hartree–Fock results for the full molecules (**12(8)**, **12(10)**, and **12(12)**) and for the corresponding series of dienes **41(*n*)** with a single all-*trans* alkane bridge. (In the latter reference compounds, the ethylenic groups are oriented as in the polynorbornane dienes **12(*n*)**.) Due to the enhanced coupling of the chromophore to the bridge made possible by the inclusion of the second relay, the splittings are larger for model **B** than for **A**. On the other hand, the β_{el} values are nearly the same for these two models, showing that the enhancement of the coupling of the chromophores to the bridge does not modify the ability of the bridge to relay the coupling. Not surprisingly, the β_{el} values for models **A** and **B** are nearly the same as those obtained from the HF calculations on the reference dienes with the single all-*trans* alkyl bridge.

The π_+ , π_- splittings decrease appreciably and the β_{el} values increase by about 30 % on going from model **B** to model **C**. The smaller splittings and their more rapid attenuation with increasing bridge length in model **C** are the result of the cross-talk interactions between the two relays. The splittings and β_{el} values for model **C** are close to those obtained from the HF calculations on the poly-

norbornane dienes, i.e., the $12(n)$ series. This shows that the destructive interference in the $12(n)$ series also results from cross-talk between the two parallel relays.

In order to understand the origin of the destructive interference, it is instructive to consider the McConnell model [17] for coupling in symmetrical chromophore–(trans-alkane bridge)–chromophore systems. In the simplest version of this model, each chromophore and each bridge site has a single active orbital, all bridge sites are assumed to be identical, and only nearest-neighbor interactions are retained. In the limit of weak coupling (Δ large, t/Δ small), the splitting arising from coupling through n bonds is given by Eq. 5.

If the NBO basis set is chosen such that adjacent orbitals overlap in-phase, as depicted in Figure 7, then the t matrix element is negative (as, for that matter, is T). The sign of Δ is taken to be positive. As a result of these conventions, for chains with an even number of bridge sites, the splitting energy $\Delta E(\pi)$ is positive (i.e., the $\pi_+ (= \pi_1 + \pi_2)$ level lies below the π_- level), whereas for chains with an odd number of bridge sites it is negative (i.e., the $\pi_- (= \pi_1 - \pi_2)$ level lies below the π_+ level). This dependence of the level ordering on the parity of the number of bridge sites is often referred to as the parity rule, which states that the level ordering follows the natural sequence (i.e., π_- above π_+) for even values of n , and the inverted sequence (i.e., π_+ above π_-) for odd values of n (Figure 31) [15, 18].

Figure 31. (a) The parity rule of through-bond coupling. The level sequence alternates with the parity of the number of σ bonds in the bridge. The labels S and A denote the symmetries of the orbitals. (b) Constructive interference resulting from two relays having the same (even) parity. (c) Destructive interference resulting from two relays having opposite parity.

Figure 32. Matrix elements describing the coupling of a p (or π) orbital of the chromophore to an all-*trans* alkane bridge. The dominant chromophore–bridge coupling is represented by T .

Within the context of the McConnell model, model **B** gives splittings precisely two times larger than those for model **A**: the presence of two noninteracting bridges coupling the chromophores leads to a doubling of the splittings. However, for both models **A** and **B**, the McConnell treatment gives $\beta_{el} = 2 \ln(|\Delta/t|)$ (see Eq. 6), and there is no change in the distance dependence of the coupling brought about by the introduction of the second, independent relay.

Consider now model **C**, focusing initially on the molecule with four σ bonds ($n = 4$) along each relay. Because the π orbitals are nearly orthogonal to the σ orbitals, the major coupling of the chromophores to the bridges is via the allylic C–C σ bonds, i.e., via bonds 2 and 3 (see Figure 32). For the purpose of delineating the origin of the destructive interference, the terminal C–C bonds of the bridges can be ignored. For this “reduced” model, the possible coupling pathways are shown in Figure 33. Pathway (a) is of the conventional McConnell-type. The extra factor of two (compared to Eq. 5) is due to the presence of the two bridges. Pathway (b) allows for one “hop” between the two relays. In the expression for the energy, this introduces an extra factor of t_2/Δ , where t_2 represents the interaction between the C–C σ bonds of the two relays (cf. Eq. 7). Because t_2/Δ is negative, the energy contribution of pathway (b) has the opposite sign from the associated with pathway

$$(a) \quad \Delta E(\pi) = -2 \frac{2T^2}{\Delta} \left(\frac{t}{\Delta} \right) \quad (\text{positive})$$

$$(b) \quad \Delta E(\pi) = -4 \frac{2T^2}{\Delta} \left(\frac{t}{\Delta} \right) \left(\frac{t_2}{\Delta} \right) \quad (\text{negative})$$

$$(c) \quad \Delta E(\pi) = -2 \frac{2T^2}{\Delta} \left(\frac{t}{\Delta} \right) \left(\frac{t_2}{\Delta} \right)^2 \quad (\text{positive})$$

Figure 33. Through-bond coupling pathways in model **C** for **12(4)**. The t_2 matrix element is responsible for the cross-talk interactions (represented by wavy lines). The energy contribution of each pathway is given as are the signs of the interactions.

(a). The multiplicative factor of four allows for the existence of four independent pathways that involve a single t_2 interaction between the two relays. Pathway (c) permits two hops between the two relays, and as a result its energy contribution acquires a factor of $(t_2/\Delta)^2$ and has the same sign as pathway (a). There are two such pathways.

For values of t/Δ and t_2/Δ appropriate for the polynorbornane dienes (-0.41 and -0.11 , respectively), the net contribution of pathways (a), (b), and (c) to the coupling is about 20 % smaller than were only pathway (a) operative. Moreover, because of the growing number of locations at which a single hop between the two relays may occur, the relative contribution of the cross-talk terms grows with increasing bridge length, leading to an increase in the β_{el} values describing the distance dependence of the electron coupling between the chromophores.

The above analysis also readily identifies why the coupling is so poor in the molecules **37(n)** and **38(n)** containing fused cyclobutane bridges. For these, the quantity t_2/Δ , which gives the contribution of a hop from one side of the cyclobutane bridge to the other, is -0.24 , over twice as large in magnitude as that in the

polynorbornane bridges. As a result, the destructive interference is considerably greater in the molecules with the cyclobutane bridge units [103, 104].

The origin of the destructive cross-talk interference occurring in the polynorbornane bridges may be recast into a very simple model based on the parity rule. Thus, the net coupling through two relays having the same parity is given by the sum of the absolute magnitude of the coupling associated with each relay and is therefore strengthened by what may be called *constructed interference* (Figure 31b). In contrast, the net coupling through relays having opposite parities is given by the difference in the absolute magnitude of the coupling associated with each relay and is therefore diminished by *destructive interference* (Figure 31c).

From Figure 33, it is easily seen that coupling pathways that make either zero or an even number of jumps from one main relay to the other, such as pathways (a) and (c), have opposite parity to those that make an odd number of jumps, such as pathway (b). Thus, pathways (a) and (c) involve coupling along two and four bonds, respectively, whereas pathway (b) involves coupling along three bonds. Consequently, the coupling in these dienes is degraded by destructive interference effects [103, 104].

Can this simple and intuitive analysis of interference effects on coupling through bridges, based on the parity rule, be used advantageously to design systems in which destructive interference is minimized or, better yet, in which the interaction between the different pathways is predominantly *constructive*?

The answer to this is affirmative, and several such systems have been devised, two examples of which are **42(n)** and **43(n)** (Figure 34). In contrast to the “standard” polynorbornane diene series **12(n)**, in which the existence of pathways of different parity destructively interfere (Figure 35a), all reasonable TB coupling pathways in **42(n)** and **43(n)** have the same parity, namely even, in the case of the former (Figure 35b) and odd, in the case of the latter (Figure 35c). Consequently, it is predicted that the net TB coupling in both **42(n)** and **43(n)** should be superior to that in **38(n)**, even though all three systems possess the same basic type of bridge. Gratifyingly, HF/3-21G calculations confirm this expectation. The calculated β_{el} values of **42(n)** and **43(n)** are *ten times smaller* than that for **38(n)** and the strength of the coupling for a given bridge length is greater for the former (Figure 34). For example, $V_{el}(= 0.5 \cdot \Delta E(\pi))$ for both **42(10)** and **43(10)** is ten times larger than that for **38(10)**, and this translates into a predicted two orders of magnitude rate enhancement for HT in the radical cations of **42(n)** and **43(n)**, relative to **38(10)** (remember that rate depends on the *square* of V_{el}). Bridges such as **42(n)** and **43(n)** deserve the epithet *superbridges*! [104].

The weak distance dependence data for π -TB interactions in **42(n)** and **43(n)** are intriguing, since they suggest that TB coupling through a single hydrocarbon chain may be greatly amplified by a proximate alkane chain which is only weakly coupled, if at all, to the chromophores (e.g., Figure 36a). In the upper part of Figure 36a, the two double bonds are connected to the same alkane bridge which is located close to an alkane chain. All inter-relay jumps begin and end on the diene bridge, and they all have the same parity. Placing two long-chain terminal alkenes in a head-to-tail arrangement (lower part of Figure 36a) will likewise result in only constructive interference effects since only an odd number of inter-relay jumps contribute sig-

		β_{el} (per bond)	$\Delta E(\pi)$ (eV) (10-bond)
38(n)		1.22	0.025
12(n)		0.68	0.078
41(n)		0.50	0.096
42(n)		0.11	0.263
43(n)		0.10	0.259

Figure 34. HF/3-21G β_{el} and $\Delta E(\pi)$ values (for $n = 10$) for various dienes.

nificantly to the overall coupling [104]. (A different type of interference between alkane chains and chromophores has been reported [105].

Indeed, such amplification may be responsible for some very small β values that have allegedly been obtained from various experimental electron transfer studies on self-assembled monolayers containing long-chain alkanes [106–109]. For example, a β value of only 0.007 bond^{-1} has been reported for electron transfer in self-assembled monolayers of viologen-terminated alkanecystamines that had been chemisorbed onto gold electrodes [109]. In such instances, amplification of TB coupling within a redox-active-terminated alkanethiol molecule may arise from cooperative through-space interactions (i.e., constructive interference) with alkane chains from neighboring adsorbed molecules, either diluent nonredox-active alkanethiols or other redox-active-terminated alkanethiol molecules (e.g., Figure 36b). Admittedly, these chains are not as close to each other as are the two main relays in

Figure 35. Schematic showing some nearest-neighbor coupling pathways for (a) **38(6)**, (b) **42(6)**, and (c) **43(6)**. All reasonable pathways have the same parity in **42(*n*)** (even parity) and in **43(*n*)** (odd parity).

42(*n*) and **43(*n*)**, but this disadvantage is possibly compensated by the presence of many more alkane chains surrounding each redox system in the monolayer. It should also be pointed out that other studies of interfacial electron transfer in long-chain alkane monolayers have reported normal β values of c. 0.95 bond^{-1} , suggesting that the distance dependence of electronic coupling through an alkane chain in self-assembled monolayer is not influenced by neighboring alkane chains [110–115]. Hopefully, the conundrum surrounding the widely disparate β values from various experimental studies on ET through self-assembled monolayers will soon be resolved.

1.8 Porphyrin and C₆₀ Chromophores

The bulk of studies of ET processes in norbornylogous systems has used the DMN and DCV chromophores. The reason for this is that, in fairly polar solvents, the magnitude of the free energy change, ΔG_{cs} , for photoinduced charge separation

in **23(n)** happens to be nearly equal in magnitude but opposite in sign to the total reorganization energy, λ [66, 67]. The exponential term in the Marcus–Hush rate expression (Eq. 2), is therefore nearly unity, making the photoinduced charge separation process for **23(n)** almost barrierless. This situation simplifies the analysis and interpretation of the ET rate data.

Nevertheless, other chromophores have been investigated and they have provided interesting insights, particularly porphyrin and C_{60} groups, since these serve as useful mimics of the cofactors present in the photosynthetic reaction center (Figure 37). Electron transfer involving porphyrins and fullerenes will be presented in more detail elsewhere in this Handbook Volume III, Part 2, Chapter 2 and Volume II, Part 1, Chapter 5 respectively), and so only a brief discussion is presented here. An excellent overview of photoinduced ET processes in C_{60} -based multichromophoric systems has been produced previously [116].

Photoinduced electron transfer reactions have been studied in the dyads **44(6)**, **45(9)**, and **46(11)**. The 6-bond porphyrin–quinone dyad **44(6)** serves as a model for aspects of ET in the photosynthetic reaction center, since congeners of these chromophores are present in the center as cofactors (Figure 37). Photoinduced ET in

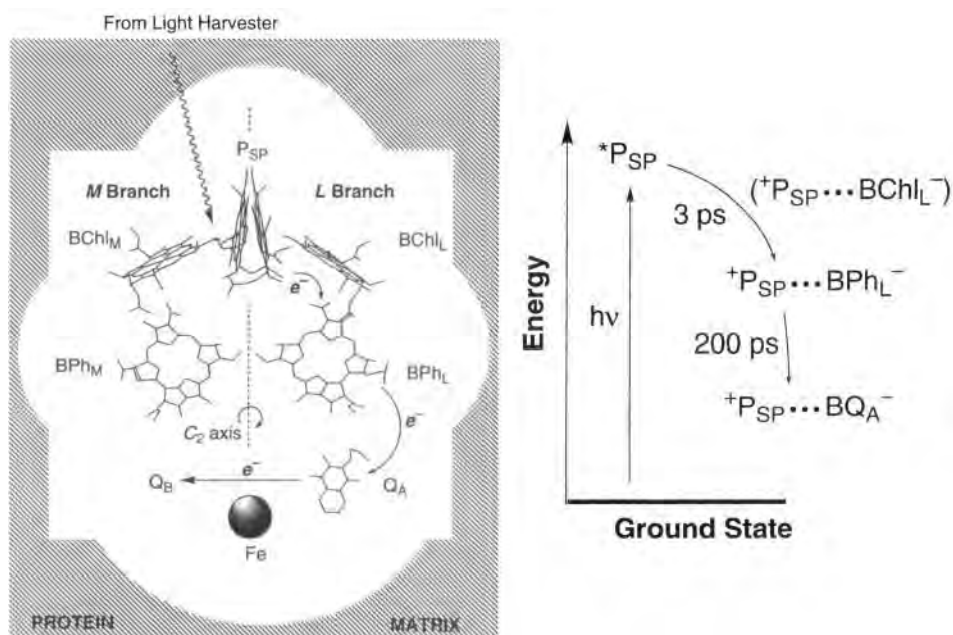

Figure 37. Schematics of the photosynthetic reaction center and the energetics of the charge separation steps, together with the individual ET rates along the *L* branch.

44(6) takes place on a nanosecond time scale (Figure 38) with high efficiency, even though the charge separation process for this system is far from barrierless [117]. The charge separation rate is comparable to that found in the photosynthetic reaction center. As with the **23(n)** series, the rapid charge separation rate observed for **44(6)** testifies to the extraordinary ability of rigid hydrocarbon bridges to mediate long-range ET processes. The charge recombination rate from the CS state of **44(6)** is about one order of magnitude slower than the charge separation rate (Figure 38).

The two C_{60} -based dyads, **45(9)** and **46(11)**, display interesting photophysical features. Rapid (subnanosecond time scale) photoinduced charge separation, from locally excited porphyrin to the C_{60} acceptor, in **45(9)** takes place in benzonitrile (Figure 38). The amazing feature of this system is not so much the rapid rate of charge separation (which is quite unusual!), but the extremely long lifetime of $0.4 \mu\text{s}$ for the CS state [118]. It is instructive to compare the rate data for this system with those for **47** (Figure 38) in which the same chromophores are connected by a single-strand *flexible* tether [119]. Whereas the charge separation rates for the two systems are similar, the charge recombination rates are dramatically different, that for **45(9)** being *three* orders of magnitude smaller than that for **47**! This huge difference in the CR rates is attributed to orbital symmetry effects. The rigidity of **45(9)** ensures that the molecule has C_s point group symmetry. Because the singlet CS state of **45(9)** has A'' symmetry, but the ground state has A' symmetry, the CR process is formally

Figure 38. Rates of photoinduced charge separation and subsequent charge recombination processes in some dyads (in benzonitrile).

symmetry forbidden and this slows down the CR rate. The flexible nature of the tether in **47** removes this symmetry restriction and the CR rate is, therefore, more rapid in this system.

The aniline- C_{60} dyad **46(11)** was no less spectacular than **45(9)**, considering the greater interchromophore separation that exists in this system (11 bonds), compared to **45(9)** (9 bonds). The photoinduced charge separation rate for **46(11)** is about $6 \times 10^9 \text{ s}^{-1}$ and the CR lifetime is 250 ns (both in benzonitrile) [120]. Why are charge separation processes involving the C_{60} acceptor so rapid in **45(9)** and **46(11)**? Intuitively, one would have predicted the opposite behavior; because of its large size, the MOs of the C_{60} chromophore have small atomic coefficients compared to those of most other chromophores in use, such as DMN. Thus, the magnitude of the coupling of the C_{60} group to the bridge would be expected to be small. However, unlike the normal chromophores, which are generally planar, the curved nature of the C_{60} surface enables it to couple to the bridge using many more atoms

than, say the DMN group, as illustrated in Figure 39a. There are 12 interactions between the orbitals of the C_{60} chromophore and the bridge, but only four interactions between the orbitals of a planar aromatic chromophore and the bridge. The result is strong coupling between the C_{60} group and the bridge, and this is manifested by the extensive delocalization of the C_{60} HOMO into the bridge (Figure 39b) [120].

Another factor which generally facilitates photoinduced charge separation in *all* dyads containing the C_{60} acceptor is the smaller internal reorganization energy, λ_i for C_{60} , compared to most acceptor groups [121]. This is probably due to the large size of the C_{60} unit; its conversion to the radical mono-anion does not produce large structural distortions. From Eq. 2, it may be seen that, for ET taking place within the normal region, the activation barrier decreases and the corresponding ET rate *increases* with *decreasing* λ_i . Since most photoinduced CS processes take place within the Marcus normal region, replacing an acceptor having a higher λ_i than C_{60} (e.g., a quinone) with C_{60} will therefore lead to an acceleration of the photoinduced charge separation process.

In contrast, charge recombination processes from CS states produced by photo-initiation normally take place within the inverted region. Thus, the small reorganization energy of C_{60} will *slow* down CR processes, relative to other acceptors having higher λ_i values.

In summary, the comparatively small internal reorganization energy of C_{60} , together with its excellent redox properties, should make the C_{60} chromophore a valuable electron acceptor component in molecular photovoltaic devices.

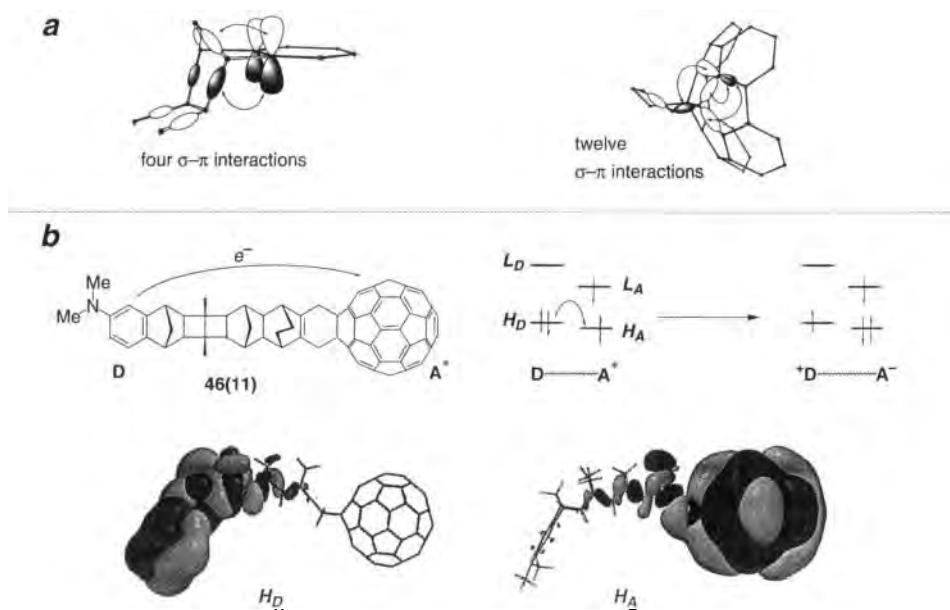

Figure 39. (a) Interactions between the orbitals of the bridge and those of a planar aromatic molecule and C_{60} . In the former, there are four interactions, two of which are shown, the other two involve the corresponding orbitals in the background. In the case of C_{60} , three interactions are shown and there are three more similar groups of three interactions involving symmetry-related orbitals, making a total of 12 interactions. (b) The active orbitals involved in photoinduced charge separation. H_D is the HOMO of the aniline donor and H_A is the HOMO of the C_{60} acceptor; the orbital plots were obtained from AM1 calculations.

1.9 Superexchange versus Molecular Wire Behavior

The rather astonishing revelation that ET can take place rapidly ($>10^9 \text{ s}^{-1}$) over inter-chromophore separations exceeding 10 \AA through saturated hydrocarbon bridges has led to the oft-asked question: If hydrocarbon bridges are able to strongly mediate ET, may they be considered to possess molecular wire (or electrical-conducting) behavior? The answer is an unequivocal no, they may not be regarded as wires. Electrical conduction through a bridge requires that the electron from the donor becomes thermally injected into the conduction band of the bridge and that it actually becomes localized within the bridge and is transported through the bridge, from donor to acceptor, by an incoherent scattering mechanism, such as a polaron. The distance dependence of the ET rate in such a molecular wire is determined by Ohmic scattering, and therefore varies inversely with bridge length [122–124]. The molecular wire mechanism is summarized in Figure 40. It is expected to operate only when the energy gap, Δ , between the donor level and the bridge conduction

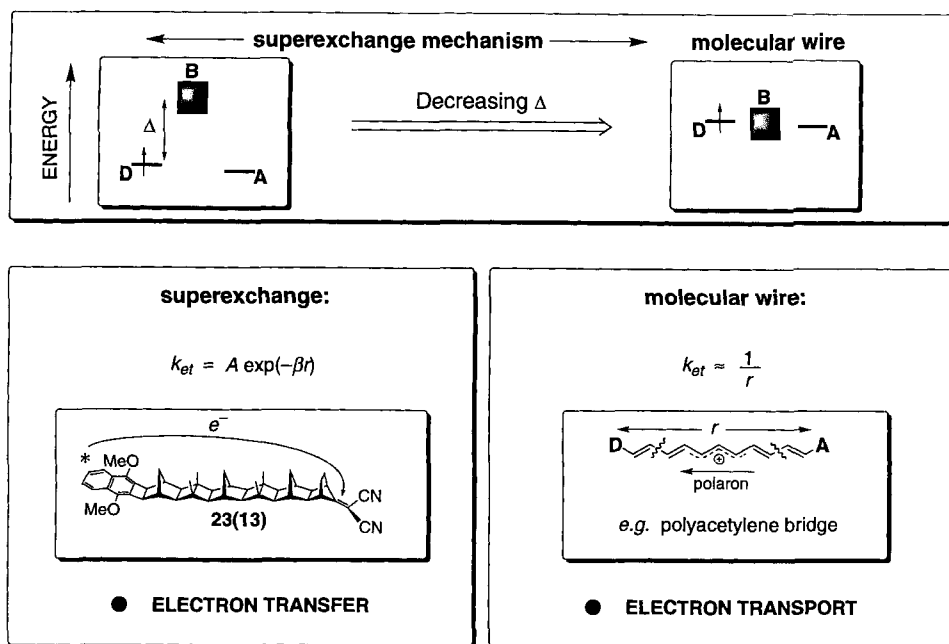

Figure 40. A schematic illustrating the difference between the superexchange mechanism and molecular wire behavior in a D–B–A dyad. Superexchange: the virtual bridge states lie well above the donor level (Δ is large) and, consequently, the electron is never localized within the bridge; instead, the electron is transferred from donor to acceptor in one coherent jump. The distance dependence behavior is exponential decay. Molecular wire behavior: The virtual bridge states are energetically comparable to the donor level (Δ is very small). In this case, the electron may be thermally injected into the bridge and becomes localized within the bridge, whereupon it moves from the donor to the acceptor incoherently as a defect, such as a polaron. The distance dependence behavior is Ohmic (varies inversely with distance).

band is very small, of the order $k_B T$. This condition is satisfied for long, conjugated bridges, such as graphite and doped polyacetylenes (Figure 40; right-hand inset).

Conjugated bridges, such as polyacetylenes, may be considered as giant chromophores whose MOs are essentially delocalized over the whole bridge. A variant of wire behavior is a bridge comprising a set of weakly coupling units (B_i), each of which is able to capture the migrating charge for a short period of time before passing it on to one of its neighboring units (Figure 41). For example, the bridge might consist of a series of small aromatic rings as units which are connected to each other by short alkane chains. Assuming that all of the bridge units are energetically nearly degenerate (Figure 41a), the migrating charge (electron or hole) randomly hops, from bridge unit to bridge unit, up and down the chain, until it is eventually irreversibly trapped by the acceptor which acts as a thermodynamic sink. Hopping between adjacent bridge units takes place through the intervening medium

Figure 41. Two charge-hopping mechanisms. The donor injects an electron (or hole) into the bridge which consists of discrete redox units. (a) The bridge units are nearly degenerate. Consequently, the injected electron (or hole) moves randomly and reversibly up and down the bridge, finally becoming irreversibly trapped by the acceptor. (b) The bridge units constitute an ordered redox cascade; the electron or hole moves essentially irreversibly along the bridge towards the acceptor.

(e.g., saturated C–C bonds, solvent molecules) by a superexchange mechanism, or even through-space, if the units are in van der Waals contact with each other.

If each single hopping step occurs over the same distance, then the hopping dynamics will display a weak distance dependence, varying inversely with respect to a small power of the number, N , of hopping steps, viz. Eq. 25 [125–127]:

$$k_{et} = N^{-\eta} \quad \eta \approx 1-2 \quad (25)$$

The electron or hole hopping mechanism may be made to take place only in one direction along the bridge by ensuring that the bridge units constitute a redox gradient (Figure 41b). Again, this mechanism avoids the exponential decay of ET or HT dynamics with distance, following a more gentle curve instead.

In contrast, in the superexchange (or TB) mechanism, Δ is very large—at least 2 eV—and so the electron cannot be thermally injected into the bridge. Instead, the electron moves coherently, in one sudden “jump”, from donor to acceptor and it never becomes localized within the bridge. The distance dependence of the ET rate for this mechanism is exponential decay (Figure 40). The conduction band for saturated hydrocarbon bridges corresponds roughly to the empty σ^* orbital levels.

Since these levels are several eV higher in energy than the π and π^* levels of most unsaturated donor systems, ET mediated by such bridges can normally occur only by the superexchange mechanism.

It is useful to introduce a nomenclature for distinguishing between ET occurring by the conduction and superexchange mechanisms. The term electron *transport* is used in the context of molecular wire behavior, while electron *transfer* is used in the context of the superexchange mechanism.

There is a simple way of visualizing the superexchange mechanism. Consider ET taking place from the dimethylaniline donor to the locally excited singlet state of C_{60} in **46(11)** (Figure 39b) [120]. The active orbitals which are primarily involved in the ET process are the aniline HOMO (H_D) and the half-filled C_{60} HOMO (H_A). Because of TB (superexchange) coupling of the bridge to the chromophores, the HOMOs of the chromophores are no longer localized to their respective chromophores, but are extended into the bridge. This is evident from the AM1 plots for H_A and H_D (Figure 39b). These orbital extensions into the bridge result in favorable overlap between H_A and H_D , and this enables ET to take place.

In principle, it should be possible to design a series of **D–B–A** dyads with a bridge, **B** possessing suitable electronic characteristics such that the superexchange mechanism prevails for short bridge lengths, but switches over to molecular wire behavior for bridge lengths exceeding a certain critical value. In order to achieve this possibility, the bridge must meet the requirement that its conduction band level falls sufficiently steeply with increasing bridge length so that it approaches the highest filled level of the donor, at which point electron transport could be the dominant mechanism (Figure 40).

A suitably constituted conjugated bridge should meet this requirement and Wasielewski's group has recently used this stratagem to demonstrate that the mechanism does, indeed, switch from electron transfer to electron transport for a critical bridge length [128]. The systems, **48(n)**, shown in Figure 42, comprise a tetracene (TET) donor and pyromellitimide (PI) acceptor, both covalently linked to *p*-phenylenevinylene oligomers of increasing length, ranging from one aromatic ring, in **48(1)**, to five, in **48(5)**. Rates of photoinduced charge separation, from locally excited TET to PI, were measured for this series in methyltetrahydrofuran. Two distinct ET behaviors were observed (Figure 42, inset). For the two shortest bridges, the charge separation rate falls quite strongly with a β value of about 0.4 \AA^{-1} . This distance dependence behavior is consistent with the operation of the superexchange mechanism for charge separation in **48(1)** and **48(2)**. Indeed, this β value is similar in magnitude to the value of $\beta = 0.57 \text{ \AA}^{-1}$, measured for interfacial electron transfer between a gold electrode and a ferrocene group covalently connected to gold by π -conjugated mercapto-oligo(phenylene-ethynylene) bridges, $\text{HS}(p\text{-C}_6\text{H}_4\text{-C}\equiv\text{C-})_m(\eta^5\text{C}_5\text{H}_5)$ ($m = 2$ or 3) [113].

In contrast, there is an abrupt change in mechanism beginning with **48(3)** for which the charge separation rate is greater than that for **48(1)**, even though the bridge in the former system is 13 \AA longer than in the latter. Moreover, extremely weak distance dependence of the charge separation rates is observed for the longer members of the series **48(3)–48(5)**, for which β is only 0.04 \AA^{-1} . The distance decay characteristics for the charge separation rates for **48(3)–48(5)** were interpreted in

Figure 42. The series of dyads used for investigating the switchover from superexchange characteristics to molecular wire behavior. Also shown is a schematic of the photoinduced charge separation rate versus donor–acceptor distance [128].

terms of molecular wire behavior: in these systems, the LUMO of the bridge approaches that for the locally excited TET chromophore and thermal injection of a TET electron into the bridge becomes energetically plausible [128].

Finally, it is instructive to compare the β value of about 0.4 Å^{-1} for photoinduced ET through the unsaturated bridges of **48(1)** and **48(3)** with the value of about 0.85 Å^{-1} (0.95 bond^{-1}) for ET through saturated hydrocarbon bridges (Eq. 23). From this comparison, one is led to conclude that the distance dependence of the superexchange mechanism for ET is about two times weaker through unsaturated

hydrocarbon bridges than through saturated hydrocarbon bridges. Perusal of Eq. 6, which is based on the McConnell model, explains why this conclusion is reasonable: the virtual ionic states of an unsaturated bridge, which are derived from π -ionizations or π -electron capture, lie closer in energy to the donor level than do the virtual ionic states of a saturated hydrocarbon bridge, which are derived from σ -ionizations or σ -electron capture (i.e., the energy gap, Δ , of Eq. 6 is smaller for the unsaturated bridge than for the saturated bridge).

1.10 Superexchange through Aromatic Bridges

With the exception of **48(1)** and **48(2)**, we have focussed only on the superexchange-mediated ET and HT processes through saturated hydrocarbon bridges. A brief survey of the participation of aromatic groups in the superexchange mechanism will now be given. A particularly clear-cut demonstration of ET occurring through aromatic bridges came from investigations of photoinduced charge separation in **49(n)** and **50(n)**, $n = 1, 2$ (Figure 43) [129]. The ET reaction occurs from the dimethylaniline donor to the locally excited singlet state of either pyrene, in the case of **49(n)**, or anthracene, in the case of **50(n)**. It was found that the ET rate decreased by a factor of 22 to 27, upon going from $n = 1$ to $n = 2$ or, equivalently, by increasing the bridge length by four bonds. This leads to a β value of:

$$\beta = 0.77 \text{ bond}^{-1} \quad (26)$$

Figure 43. Some multichromophoric systems for investigating superexchange through aromatic groups.

This value is significantly smaller than the β value of 0.95 bond^{-1} for saturated hydrocarbon bridges (Eq. 23), and it reflects the lower energies of the virtual ionic states of aromatic molecules compared to saturated hydrocarbon molecules (vide supra and Eq. 6). The value of β for these systems is, however, noticeably larger than that measured for photoinduced ET in **48(1)** and **48(2)**. These elegant studies have been extended to cover other aromatic-bridge systems [130].

The rates of photoinduced charge separation, from the locally excited porphyrin donor to the naphthoquinone acceptor, were measured for the *syn* and *anti* stereoisomers of **50** and **51** (Figure 43). The charge separation rates for **50** and **51** were nearly identical for both sets of isomers. Interestingly, the charge recombination rates for **51-anti** and **51-syn** are about 3.5 times larger than those of **50-anti** and **50-syn**, respectively. This observation was explained in terms of a superexchange mechanism involving an electronic configuration of the bridge in which the virtual cationic state of dimethoxybenzene contributes (e.g., Figure 6) [72].

A spectacular example of superexchange is believed to occur during photoinduced ET in the C-H₂P-Im carotenoid-porphyrin-pyromellitimide trichromophore (triad) **52** (Figure 44) [131]. Selective photoexcitation of the carotenoid chromophore led to the formation of the giant charge-separated state $^+\text{C-H}_2\text{P-Im}^-$ within a few picoseconds. This rapid formation of the giant CS state was

Figure 44. Further examples of multichromophoric systems for investigating superexchange through aromatic groups.

interpreted in terms of direct, long-range ET from the singlet excited state of the carotenoid, *C , to **Im** mediated by a superexchange interaction involving the π -MOs of the H_2P group. An alternative mechanism to the superexchange-mediated long-range electron transfer process is (reversible) singlet–singlet excitation energy transfer from *C to H_2P , to form $C-H_2P^*-Im$, followed by ET from the porphyrin to **Im**, which generates the intermediate CS state $C-H_2P^+-Im^-$. Thermal hole transfer from H_2P^+ to **C** produces the product giant CS state. The correctness of the superexchange mechanism received support from experiments which selectively excited the H_2P chromophore where it was found that the rate of formation of $^+C-H_2P-Im^-$ from $C-H_2P^*-Im$ is considerably slower, compared with that starting from $^*C-H_2P-Im$ [131].

Photoinduced ET from the locally excited porphyrin to the naphthoquinone in the *syn* and *anti* stereoisomers of **53** was studied in order to ascertain the consequence of placing a phenyl group in the space between the redox couple in **53-syn** (Figure 44) [132]. The edge-to-edge distances between the phenyl and the porphyrin or quinone rings in the *syn* isomer are in the range of 2.5–4.2 Å. Therefore, it is possible for ET to take place from porphyrin to quinone in the *syn* isomer by a superexchange process involving the phenyl group's orbitals. However, the rate of charge separation for **53-syn** is almost the same as that for a reference compound in which the phenyl group is absent. It was concluded that superexchange involving the phenyl ring does not occur in either isomer of **53**, and that charge separation in these molecules takes place by superexchange through the C–C σ bonds of the bridge.

The failure to observe superexchange-mediated ET through the phenyl group in **53-syn** may be due to the need for the aromatic ring to adopt a more favorable orientation with respect to the donor and acceptor chromophores, or it might be due to the fact that the virtual anionic states of the phenyl group are not low enough in energy to mix strongly enough with the excited donor state. An interesting case in which, perhaps, a more favorable orientation of the aromatic group does result in superexchange-mediated ET has recently been reported using a supramolecular assembly consisting of the clip-shaped receptor molecule **55** and the aromatic guest molecule hexyl 3,5-dihydroxybenzoate **56** (Figure 45) [133, 134].

Steady-state fluorescence studies of **55** in carbon tetrachloride gave a fluorescence quantum yield identical with that observed for the model system **54** in which the quinone acceptor has been replaced by a dimethoxybenzene group. This result shows that no photoinduced ET, from the locally excited porphyrin donor to the benzoquinone acceptor, is taking place in **55** in CCl_4 solvent. Addition of the guest hexyl 3,5-dihydroxybenzoate **56** to a solution of **55** in CCl_4 results in >75 % quenching of the porphyrin fluorescence. In contrast, the fluorescence for the model system **54** in CCl_4 did not diminish in intensity upon addition of the guest **56**. The fluorescence quenching observed for **55** in the presence of the guest **56** was therefore attributed to the occurrence of rapid photoinduced electron transfer taking place in the host–guest complex **57**. Hydrogen bonding between the two hydroxy groups of **56** and the pair of imide carbonyl oxygen atoms of **55** place **56** in face-to-face orientation with respect to the porphyrin and quinone chromophores, an ideal orientation for promoting superexchange coupling between the three π -systems.

Figure 45. A clip-shaped dyad **55** for investigating superexchange through aromatic systems. The resorcinol **56** becomes complexed to **55** by H-bonding interactions, shown schematically by **57**. Fluorescence quantum yields (CCl₄) reveal that the porphyrin donor fluorescence is strongly quenched in **57**, indicating that ET from the porphyrin to the quinone is occurring through the complexed resorcinol by a superexchange mechanism [134].

1.11 Electron Transfer Mediated by π -Stacks in DNA

Imagine a columnar stack of aromatic rings placed about 3.4 Å apart in parallel planes (Figure 46). How well would such an array mediate ET and HT processes, and by what mechanism would the charge transfer take place, superexchange or by a conduction-like mechanism with the electron or hole “hopping” between aromatic rings?

This problem is receiving intense scrutiny because of its relevance to ET and HT processes in duplex DNA in which the base pairs are approximately stacked in the manner described above [135]. Although the main biological function of DNA is not the transfer of electrons or holes, there is mounting evidence that it may suffer long-range oxidative damage by the migration of holes through the π -stack over extremely large distances (>50 Å) [135–139].

Figure 46. Schematic of the mediation of ET by a π -stack of aromatic rings, such as the base pairs of duplex DNA. The D and A groups associated with the DNA molecule may be covalently linked to the helix, they may be intercalators, or they may be DNA base pairs.

Because duplex DNA may be regarded as a covalently linked multichromophoric system comprising organic chromophores (DNA base pairs), it is appropriate to present a brief discussion of the mechanism of ET and HT in this biopolymer, even though it is treated in greater depth in Volume III, Part 1, Chapter 5 of this Handbook. The discussion will be restricted to the distance dependence of ET and HT dynamics and the question of whether the mechanism of ET and HT reactions is superexchange or charge “hopping”.

Whether ET or HT in DNA occurs by charge hopping or superexchange will largely depend on the relative energy levels of the bridge states (i.e., the DNA bases) and the initial state (donor state). If the bridge states are energetically higher than the initial state, then the electron or hole cannot reside in the bridge, and the charge transfer must occur by a superexchange mechanism i.e., by a single coherent “jump”, from donor to acceptor. The charge transfer dynamics will then follow an exponential decay with distance according to Eq. 4. If, on the other hand, the bridge and donor levels are similar, then thermal injection of an electron or hole into the bridge may take place, and the transport will occur by a hopping mechanism. The hopping dynamics will display weak distance dependence, varying inversely with respect to a small power of the distance according to Eq. 25.

Thus, because of its exponential distance dependence, superexchange-mediated ET and HT in DNA should not be significant for donor–acceptor separations exceeding 15 Å, whereas ET and HT occurring by a hopping mechanism are expected to be much longer range processes, extending beyond 50 Å.

The composition and sequence of the base pairs in DNA should have an important effect on the ET and HT mechanisms. With regard to HT, guanine (*G*) is much more easily oxidized than adenine (*A*) or thymine (*T*); consequently, hole injection into the DNA helix will generate a $G^{+\bullet}$ radical cation. The hole may now randomly

walk over large distances along the DNA helix by hopping between adjacent **G** bases, which have similar redox properties. The hole, however, will never reside on either **A** or **T** bases since their oxidation potentials are higher than that of **G**. The **A–T** base pairs serve, instead, as a superexchange medium through which the charge tunnels between two adjacent **G** bases. The rate of hopping between a pair of adjacent **G** bases is therefore governed by the number of intervening **A–T** base pairs according to the superexchange mechanism. The overall HT hopping rate between donor and acceptor is therefore determined by the largest number of **A–T** base pairs between a pair of adjacent **G** bases in the charge transfer pathway. If each hopping step in an HT pathway involves the same number of intervening **A–T** base pairs, then the hopping mechanism obeys the distance dependence relationship given by Eq. 25 [140].

A number of distance dependence studies have been carried out using synthetic DNA duplexes. In most of these investigations, the data were found to be consistent with the superexchange mechanism since the ET and HT rates followed exponential decays with increasing distance.

An example of the types of distance dependence experiments that are being carried out on DNA is shown in Figure 47 [141]. The DNA strand is a synthetic 6-mer duplex comprising five **A–T** base pairs and a single **G–C** base pair located at various positions along the helix. The duplex is capped by a stilbene hairpin which serves as a photooxidant. Photoexcitation of the stilbene group initiates electron transfer from the **G** donor to the locally excited stilbene acceptor (or equivalently, HT from stilbene to **G**). Importantly, neither **A** nor **T** is able to transfer an electron to the locally excited stilbene since their oxidation potentials are too high. By varying the stilbene–**G** separation it was possible to obtain a distance dependence for the HT rate, which turned out to be exponential with $\beta = 0.64 \text{ \AA}^{-1}$ [141].

A variety of distance dependence studies of ET through DNA, involving different base-pair sequences and different redox couples, have produced β values ranging from $<0.2 \text{ \AA}^{-1}$ to 1.4 \AA^{-1} , i.e., (in units of \AA^{-1}) <0.2 [142–144], 0.64 [141], 0.73

Figure 47. Schematic of photoinduced ET process in a synthetic 6-mer comprising five **A–T** base pairs and one **G–C** base pair located at various distances from the stilbene acceptor [141]. The locally excited stilbene is a potent enough acceptor to effect an ET from **G**, but not from **A** or **T**.

[145], 0.88 [146], 1.0 [147, 148], and 1.42 [149]. With the exception of the very low β value of $<0.2 \text{ \AA}^{-1}$ by Barton and colleagues [142–144], the remaining studies give β ranging from 0.64 – 1.42 \AA^{-1} , suggesting that electron transfer in DNA is protein-like (β for ET in proteins ranges from 0.9 – 1.6 \AA^{-1} [150, 151]; see also Chapter 1 in Section 3.1 of this Handbook).

The large spread in experimentally determined β values for electron transfer in DNA contrasts markedly with the rather narrow range of β values measured for ET occurring through saturated hydrocarbon bridges by the superexchange mechanism (vide supra). Application of simple McConnell theory shows that this large spread is still consistent with the operation of a superexchange mechanism for ET in DNA. From Eq. 24, the sensitivity of β varies inversely with the donor–bridge energy gap Δ . For saturated hydrocarbon bridges, this gap is large and so β will be less sensitive to variation in the energy of the donor. For DNA, however, the virtual ionic states of the base pairs are π -type; consequently, Δ is much smaller and changes in the donor energy should markedly affect the magnitude of β .

Although the β values listed above are consistent with the operation of a superexchange mechanism, the very low values reported by Barton et al. could be interpreted in terms of a hopping or molecular wire mechanism. Indeed, although one theoretical treatment predicts DNA to behave like a protein [150], another predicts that, under certain conditions, a distance-independent ET mechanism term arises which eventually dominates the exponentially distance-dependent superexchange mechanism [122]. Recent femtosecond photoinduced ET studies by Zewail and Barton on DNA possessing an intercalated, covalently tethered ethidium (acceptor) and a 7-deazaguanidine donor revealed the presence of an ultrarapid ET component whose rate was distance-independent for donor-acceptor separations less than 17 \AA [152]. This study lends support to the conjecture that DNA might display wire behavior.

Recent experiments have demonstrated the operation of the hole-hopping mechanism between **G** bases in DNA [125, 140]. In these experiments, Norrish I photocleavage of an acylated nucleoside in a synthetic duplex DNA leads to the formation of a sugar radical (Figure 48a) which then suffers heterolysis to give the radical cation. This sugar radical cation initiates the HT process by transferring the positive charge to a nearby **G** base (Figure 48a). The hole is then free to leave the initial site, $\text{G}_{23}^{+\bullet}$, and wander through the DNA molecule, hopping between adjacent **G** bases; this meandering is only terminated when the hole encounters a **GGG** unit and is irreversibly trapped (**GGG** has a lower oxidation potential than **G**). By varying the length, composition and sequence of the π -stack spanning $\text{G}_{23}^{+\bullet}$ and **GGG**, the distance dependence of the HT dynamics could be measured (Figure 48b).

For **58(1)**–**58(4)**, in which one to four **A–T** base pairs are inserted between $\text{G}_{23}^{+\bullet}$ and **GGG**, the relative HT rate from $\text{G}_{23}^{+\bullet}$ to **GGG** follows an exponential decay with increasing **G**₂₃–**GGG** separation, with an associated β value of 0.7 \AA^{-1} . The operation of the superexchange mechanism for HT in this series of DNA molecules is to be expected since the **A–T** radical cation states are significantly higher in energy than $\text{G}^{+\bullet}$.

Replacement of one of the four **A–T** base pairs in **58(4)** with a **G–C** base pair, to give **59(4)** and **60(4)**, led to a two orders of magnitude increase in the HT rate

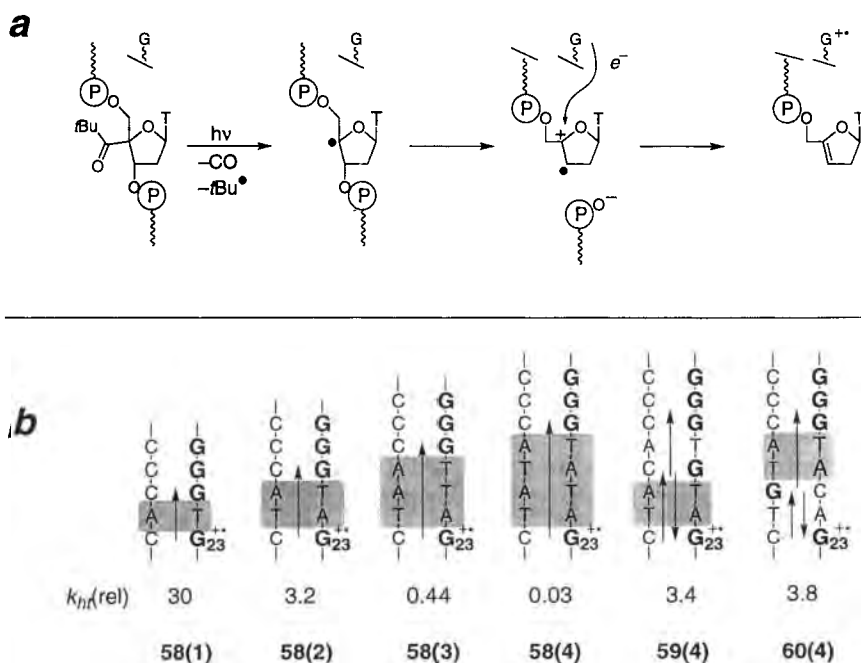

Figure 48. Exploring hole transfer propagation through DNA [125]. (a) The hole is generated by photocleavage, followed by heterolysis and subsequent hole generation at a nearby *G* base. (b) Relative rates of HT, from $G_{23}^{\bullet+}$ to *GGG*, through various DNA duplexes. The shaded areas highlight the longest path between adjacent *G* bases.

relative to **58(4)**. This rate enhancement was attributed to reversible hole hopping between G_{23} and the inserted *G* unit [125]. The longest superexchange pathway in both **59(4)** and **60(4)** has been reduced to only two *A–T* base pairs, compared to four in **58(4)**. It is not surprising, therefore, that the HT rates for **59(4)** and **60(4)** are larger than that for **58(4)** and almost the same as that for **58(2)**, which also has a superexchange pathway comprising two *A–T* base pairs.

By using synthetic duplex DNA molecules in which every hopping step between adjacent *G–C* pairs involves the same number (two) of intervening *A–T* pairs, the validity of Eq. 25, with $\eta = 1.7$ was demonstrated [140].

In summary, these experiments suggest that the hole (or electron) is able to hop incoherently among the *G* bases in a random walk which gives rise to a weak algebraic decay of the HT rate with distance (Eq. 25, $\eta = 1.7$). Moving the electron from one *G* unit to the next requires the operation of the superexchange mechanism, because of the unfavorable redox properties of the intervening *A* and *T* bases. Because of the strong distance dependence of the superexchange mechanism, HT dynamics will be sensitive to the base sequence; the higher the density of *G* bases along the HT pathway, the faster will be the HT rate and the further the hole will be able to travel. Indeed, by judicious placement of *G* units, charge transfer has been observed to occur rapidly over distances exceeding 54 Å [140].

With regard to electron transfer in DNA radical anions (as opposed to HT in the radical cations), the hopping mechanism involves the intermediacy of radical anions of the *C* and *T* bases which have similar reduction potentials. Since one of these bases is present in each base pair, it is predicted that ET proceeding by the hopping mechanism would not be sequence-dependent [127, 140]. Indeed, it has been predicted that measurable hole hopping through DNA could occur over distances as large as 300 Å [127].

1.12 Electron Transfer Mediated through Hydrogen Bonds

Given that ET through proteins is fundamental to many biological processes, and that H-bonds are prevalent in proteins, it is important to determine how efficiently ET can be mediated by H-bonds. The subject of ET in H-bonded and ion-paired systems is presented in Volume III, Part 2, Chapter 4 of this Handbook. Of the numerous studies which have been reported [153–161], that by Therien is of particular relevance to this chapter because it provides a comparative study of ET mediated by saturated bonds and by H-bonds [161]. Therefore, the Therien study will be briefly described here.

The Zn(II)porphyrin–bridge–Fe(III)porphyrin systems, together with their photoinduced ET rate constants, are shown in Figure 49. The ET rate constant for the H-bonded system **61** is comparable to that for **62**, which possesses a partially unsaturated hydrocarbon bridge, whereas the rate for **63**, which contains a fully saturated bridge, is notably slower than the ET rate for **61**. These data suggest that electronic coupling mediated by H-bonds is significant and that, therefore, H-bonded networks may provide dominant pathways for ET in proteins [161].

The observation that ET through a hydrogen-bonded complex is faster than that through a saturated bridge of equivalent length is somewhat surprising, since the strength of the electronic coupling through an H-bond is probably less than that through two geminal C–C bonds [162]. However, it is possible that the diminished ET rate in **63**, compared to **61**, is due to destructive interference in **63**, produced by the TB coupling pathway proceeding through the central ring-fusion bond in the bicyclo[3.3.0]octane unit.

1.13 The Effect of Orbital Symmetry on ET Dynamics

Orbital symmetry can influence ET dynamics through the electronic coupling term, V_{el} , and it is of considerable interest to ascertain the degree of this influence. Covalently linked dyads provide the best way of achieving this experimentally.

The rigid, symmetric norbornylogous systems are well-suited for investigating orbital symmetry effects, two examples of which are shown in Figure 50. Charge

Figure 49. Three dyads possessing Zn(II) porphyrin donor and Fe(III) porphyrin acceptor linked by (from top to bottom) H-bonded bridge, a partially unsaturated bridge and a saturated bridge [161].

recombination from the CS state of **23(8)** is symmetry forbidden since the ground and CS states have opposite state symmetries. This arises because the DMN HOMO and the DCV LUMO in the CS state are each singly occupied but have different symmetries with respect to the molecular plane of symmetry, i.e., a'' and a' , respectively. Consequently, the overall symmetry of the CS state is A'' , whereas that for the ground state is A' .

That charge recombination in the CS states of the series **23(n)** is symmetry forbidden is partly responsible for the unusually long lifetimes observed for the CS states (see Figure 17). The extent to which this orbital symmetry forbiddenness influences the CR process in **23(n)** was gauged by comparing the magnitude of the electronic coupling element, V_{el} for CR in **23(8)** with that for **64(8)**. In the latter system the CR process is symmetry allowed because the maleonitrile LUMO has a'' symmetry, thereby endowing both the CS and ground states of **64(8)** with A' symmetry. From the analysis of charge transfer fluorescence bands that accompanied CR in both **23(8)** and **64(8)**, the V_{el} values for CR in these molecules were calculated to be 36 and 129 cm^{-1} , respectively (in benzene). This result implies that orbital

Figure 50. Dyads used for investigating orbital symmetry effects on ET rates. Center: Orbital symmetries of the active MOs involved in the ET processes for **23(8)** and **64(8)**.

symmetry influences electronic coupling by a factor of 3.6 and the charge recombination rates by a factor of 13 (i.e., the CR rate varies with the square of the electronic coupling; see Eq. 2) [163].

The second example of orbital symmetry effects concerns photoinduced charge separation in the norbornylidene dyads, **65(7)** and **66(7)**, which is symmetry-forbidden in the former system but symmetry allowed in the latter. In these systems, orbital symmetry effects are more pronounced than in **23(8)** and **64(8)**, amounting to a 28-fold modulation in the magnitude of V_{el} [164].

A final example of orbital symmetry-forbidden ET is photoinduced ET in **67** (Figure 51). The electronic coupling for photoinduced ET in this molecule should be zero, if this system retains local D_{2d} symmetry within the bismethyleneadamantane unit. However, the experimental photoinduced intramolecular ET rate in this system is extremely rapid, $>10^8 \text{ s}^{-1}$ [165].

Although the data for **23(8)** and **65(7)** (Figure 50) reveal that orbital symmetry does have an effect on ET rates, the rates can still be rapid, nevertheless. For example, the orbital symmetry-forbidden rate of photoinduced ET in **23(13)** is a massive 10^8 s^{-1} .

Clearly, certain vibrational motions (vibronic coupling) in these systems remove the offending symmetry constraint, and lead to a substantial magnitude of V_{el} [166, 167]. Intriguing questions then arise from these experimental data, such as: Is there more than one vibrational mode responsible for generating strong electronic cou-

Figure 51. Photoinduced ET in **67** occurs rapidly [165], even though the process is formally forbidden by orbital symmetry. The dynamics of the ET process for **67** is modeled by molecular dynamics calculations of hole transfer in the bis-methyleneadamantane radical cation **69**.

pling? Which modes are primarily responsible for producing the coupling? Answers to these questions are amenable to experimental verification through judicious use of isotopic labeling.

Recently, Jones et al. have described a molecular dynamics (MD) model, which incorporates the trajectory surface hopping (TSH) method (MD-TSH), that shows promise in answering a number of important questions in ET, including those mentioned above [168]. For example, this method has been applied to the dynamics of thermal hole transfer in the bismethyleneadamantane radical cation **68** which serves as a model for **67**. It was found that, instead of V_{el} being zero at the avoided crossing for HT in **68**, it possessed an average value of 0.01 eV. This large value for V_{el} is achieved mainly through the symmetry-breaking torsional vibration about the terminal methylene group of the one-electron π -bond, e.g., **69** [169].

1.14 Effect of Donor–Acceptor Orientation on ET Rates

It is fair to say from the above discussions that the distance dependence of ET dynamics has been extensively measured and explained in terms of the super-exchange (TB) mechanism. These investigations, involving covalently linked multi-chromophoric systems, have also shed light on aspects of the mechanism of the

early ET events occurring in the photosynthetic reaction centres (PRCs) of certain photosynthetic bacteria (see Figure 37).

These ET events are observed to take place on a picosecond time scale, with near unit efficiency, over interchromophore separations exceeding 10 Å. Moreover, ET in the PRC takes place with exquisitely controlled directionality: The primary ET cascade, emanating from the P_{SP} “special pair”, and terminating at the quinone groups, Q_A and Q_B , takes place exclusively along the so-called *L* branch, rather than along the *M* branch, even though both branches are apparently related by near-perfect C_2 symmetry (Figure 37). Since the chlorophyll-like and quinone co-factors are clearly not connected to each other by bonds, conjugated or otherwise, how does the ET process take place so rapidly and how does it “know” which path, the *L* or *M* branch, to take? Although the precise mechanism of ET in the PRC remains unknown, the finding that superexchange-mediated ET through saturated bonds and proteins [151] is a long-range and efficient process lends strong support to the conjecture that the dynamics and directionality of ET in the PRC are controlled by the protein matrix surrounding the center.

Another factor which might be important in modulating ET dynamics is the donor–acceptor orientation. Again, rigid covalently linked dyads are playing a key role in this type of investigation.

Sakata and colleagues have synthesized and studied the photophysics of the dyads **70–73** (Figure 52) [170, 171]. Two types of rigid hydrocarbon bridges were employed to maintain the benzoquinone acceptor at a fixed distance and orientation relative to the porphyrin ring. The orientation of the bridge in each molecule is fixed owing to severe steric congestion between the two neighboring porphyrin

Figure 52. Some porphyrin–quinone dyads used for investigating orientation effects on ET dynamics.

methyl groups and the intervening *meso*-phenyl group which forces the latter into a near-90° orientation with respect to the plane of the porphyrin ring. The spiro[4.4]nonane (SP) and *trans*-decalin (TD) bridges provide very similar donor–acceptor distances, and each has the same number of C–C bonds (four) connecting the two chromophores to the *meso*-phenyl group; however, the SP and TD bridges provide porphyrin–quinone orientations which differ by 90°.

For the free base porphyrin-systems **70a–73a**, it was found that the rate of photoinduced charge separation was greater for the SP systems than for the corresponding TD system: $k_{cs}(\mathbf{70a}):k_{cs}(\mathbf{71a}) \approx 5$ and $k_{cs}(\mathbf{72a}):k_{cs}(\mathbf{73a}) \approx 9$ [171]. Similarly, for the zinc porphyrin molecules, **70b–73b**, the rates of both photoinduced charge separation and subsequent dark charge recombination were greater for the SP molecules than for the corresponding TD molecules.

Because of the near-identical driving forces for, and donor–acceptor distances in, the SP and TD molecules, the rate differences were attributed to differences in the electronic coupling term, V_{el} , rather than to any differences in the Franck–Condon factor. The coupling may be partitioned into a through-bond (through-bridge) component, a direct through-space interaction between the porphyrin and quinone and a superexchange interaction occurring through the intervening solvent molecules between the porphyrin and quinone moieties (*vide infra*). Calculations indicated that TB coupling is approximately the same magnitude through both SP and TD bridges. Consequently, it was concluded that the orientation dependence of the ET rates was due to a combination of through-solvent and through-space effects [170, 171].

It is noteworthy that orientation effects do not seem to be manifested in the series of dyads **32(n)**, even though the quinone–porphyrin orientation for even values of n differs from that for odd values of n by 90°. This deduction was made on the basis that the rate of photoinduced charge separation for **32(n)** followed a good exponential decay with increasing n , with all points associated with both even and odd values of n falling on the same straight line [84].

The dependence of ET rates on the dihedral angle between the two rings of the free base porphyrin donor and the Fe(III) porphyrin acceptor in **74** has been investigated (Figure 53) [172]. The dihedral angle was varied by using the biphenyl bridges shown in the lower part of Figure 53; each of these biphenyl bridges has a definite dihedral angle between the two aromatic rigs, determined by either structural or steric factors. It was found that the rate of photoinduced ET, from locally excited free base porphyrin to Fe(III) porphyrin followed a $\cos 2\theta$ dependence (θ is the dihedral angle about the biphenyl moiety) and was a minimum for $\theta = 45^\circ$ and a maximum for $\theta = 0^\circ$ and 90° . This $\cos 2\theta$ dependency of ET rate is a result of symmetry arguments applied to the nodal structures of the porphyrins and holds, no matter what the mechanism of ET in **74** happens to be, through-space or through-bond (although it is almost certainly the latter which prevails) [173]. These rate data show that changing the dihedral angle from 45° to 0° and 90° results in rate enhancement factors of about 15 and 12, respectively [172].

In summary, orientation effects on ET rates are important, amounting to modulation of rates by factors as large as 20. They are certainly as important as bridge configuration effects (*i.e.*, the all-*trans* rule) and orbital symmetry effects in influ-

Figure 53. A bisporphyrin dyad for investigating orientation effects on ET dynamics. The dihedral angle between the two porphyrin rings is adjusted by varying the biphenyl bridge [172].

encing ET dynamics. However, a clearer understanding of the origin of orientation effects on ET dynamics is needed.

1.15 Modulation of Electron Transfer Dynamics by Electric Fields

We now turn to another important influence on ET dynamics, electric fields. It is reasonable that the presence of a strong electric field should influence the dynamics of charge separation processes because the dipole moment associated with the newly formed CS state will interact with the field. This interaction will modify the barrier height for the charge separation process. Indeed, it has been postulated that electric field effects might be the cause of the observed directionality of electron transfer in the photosynthetic reaction centre (see Figure 37).

Figure 54. The helical oligopeptide-based dyads used for investigating electric field effects on ET dynamics [174].

The dependence of ET rates on the strength and direction of the electric field has been investigated using the rigid synthetic helical peptides **75** and **76** (Figure 54) possessing covalently linked dimethylaniline (**An**) donor and pyrene (**Pyr**) acceptor [174]. The photoinduced charge separation process involves transfer of an electron from the aniline to the locally excited singlet state of the pyrene (**Pyr***) to give the CS state, $^+\text{An-peptide-Pyr}^-$. In **75**, the dipole of the resulting CS state is aligned antiparallel to the electric field vector generated by the peptide backbone. The CS state of **75** is therefore stabilized by the presence of the electric field (the positive and negative ends of which are located at the nitrogen and carboxylate termini, respectively). In **76**, the positions of the two chromophores are switched, everything else remaining unchanged; in this case, the CS state is now destabilized (relative to **75**) by interaction with the electric field.

Consequently, it is predicted that the charge separation rate should be greater for **75** than for **76**, since the former is associated with a more negative free energy change and therefore, from Eq. 2, with a lower activation barrier. In agreement with qualitative prediction, it was found that the ratio of the photoinduced charge separation rates $k_{cs}(\text{75}):k_{cs}(\text{76})$ is 27 in tetrahydrofuran (THF), a low-polarity solvent, but fell to only 5 in the more polar methanol solvent [174]. The attenuation of the ET rate ratio with increasing solvent polarity is also consistent with the electric field mechanism since the interaction between the electric field of the protein and the dipole of the CS state will be weakened in more polar solvents.

Confirmation that electric field effects were responsible for the enhanced ET rate in **75** relative to **76** was obtained by repeating the ET measurements in THF containing various quantities of water—a solvent which is known to cause protein unfolding and hence to a loss of electric field. Indeed, the $k_{cs}(\mathbf{75}):k_{cs}(\mathbf{76})$ ratio fell from 27 in neat THF to only about 1.8–2.4 in THF–water mixtures [175].

Electric field effects are finding uses in molecular switches. Thus, Wasielewski et al. have synthesized a covalently linked tetrachromophoric system **77**, D_1 – A_1 – A_2 – D_2 . Selective photoinduced ET can be made to take place to give either of the two radical mono-ion pairs, $^+D_1$ – A_1^- – A_2 – D_2 or D_1 – A_1 – A_2^- – D_2^+ . However, formation of the bis-ion pair $^+D_1$ – A_1^- – A_2^- – D_2^+ is completely prevented by the electric field of the neighboring ion pair in the mono-ion pair precursor [176]. That is, the neighboring field causes the second photoinduced charge separation step to become endergonic.

A small covalently linked triad which exhibits unidirectional, path-selective photoinduced ET has been described [177]. The singlet excited state of the 4-aminonaphthalimide fluorophore in **78** and **79** acts as an acceptor and the diethylamino and morpholino groups as donors, although the former is a more potent donor than the latter. It was found that in each molecule, photoinduced ET always took place from the dialkylamine that is attached to the 4-amino position, irrespective of the difference in driving force for the two dialkylamino groups. This observation was attributed to the presence of the large excited state dipole of the 4-aminonaphthalimide whose magnitude and direction only favors ET taking place in the direction from the donor which is attached to the 4-amino position [177].

1.16 Design of Dyads with Rapid Solvent-Independent Charge Separation

An interesting challenge with obvious applications is the following: Is it possible to design, from first principles, a dyad for which the rate of photoinduced charge separation is virtually solvent- and temperature-independent? It has, indeed, been shown that it is possible to do so, at least within the context of simple Marcus–Hush theory [67]. Recalling from the Marcus–Hush equation (Eq. 2) that a barrierless ET process means that $-\Delta G_{et} = \lambda$ ($\lambda = \lambda_i + \lambda_s$), it was shown that those factors which render a charge separation process optimally rapid and barrierless also make the rate virtually solvent-independent. This result implies that, for a given system, there is a unique value for a quantity called the polar free energy change, P_{opt} , that will make the reaction rate-optimal and solvent-independent. P_{opt} for a particular system represents the limiting value of ΔG_{et} for charge separation across an infinite distance in polar media and is readily accessible from the independently determined redox potentials and excitation energies of the individual donor and acceptor chromophores. From Marcus–Hush theory, together with the condition that the ET process is barrierless, the expression (Eq. 27) may be derived [67]:

$$P_{opt} \approx -\lambda_i - \frac{e^2}{n^2} \left(\frac{1}{r} - \frac{1}{R_c} \right) \quad (27)$$

where λ_i is the internal reorganization energy of the dyad, e is the charge of the electron, n is the refractive index of the solvent (normally taken to be equal to 2.0), r is the average ionic radius of the chromophores, and R_c is the center-to-center interchromophore separation. The weak temperature dependence of ET dynamics for systems which satisfy Eq. 27 follows from the fact that such ET processes are barrierless and, therefore, from Eq. 2, the ET rates depend only on $T^{-1/2}$.

The importance of Eq. 27 is that it relates P_{opt} , which can be experimentally determined from the redox and photophysical properties of the donor and acceptor chromophores, to R_c ; that is for a preset interchromophore separation, R_c , the redox and photophysical properties of the chromophores must be chosen so that they give a value of P_{opt} which is identical to that calculated from Eq. 28. Conversely, for a given pair of chromophores, there is a unique value of R_c for which the free energy of activation for photoinduced charge separation in the dyad is largely solvent-independent.

This model was used successfully to explain the different solvent dependencies of the rates of photoinduced charge for the dyad **23(8)** and the naphthalene analogue (i.e., the methoxy groups are replaced by hydrogens) [67]. Equation 27 has recently been used to explain the interesting contrasting photoinduced electron transfer properties of the two closely related covalently linked porphyrin–naphthoquinone dyads **80** and **81** [178]. It was found that dyad **80**, whose quinone carbonyl groups are 6.7 Å from the center of the porphyrin donor, exhibits photoinduced ET whose

rates are practically solvent- and temperature-independent. In contrast, the rates of photoinduced ET in the dyad **81**, whose carbonyl groups are further removed from the porphyrin center (8.8 Å) display much stronger temperature and solvent dependence. It was found that the R_c value for **80** (6.7 Å) more closely satisfies Eq. 27 than did that for **81**—the former proceeded under barrierless conditions, whereas the latter gives a P value which differs from P_{opt} by 0.17 eV [178].

1.17 Verification of the Marcus Inverted Region

From Eq. 2, the activation free energy for an ET process is given by:

$$\Delta G_{et}^\ddagger = \frac{(\Delta G_{et} + \lambda)^2}{4\lambda} \quad (28)$$

Electron transfer reactions for which $-\Delta G_{et} < \lambda$ are said to take place in the Marcus normal region and their rates increase with increasing exergonicity, becoming optimal (barrierless) when $-\Delta G_{et} = \lambda$. When the reaction becomes even more exergonic, then $-\Delta G_{et} > \lambda$ and an activation barrier reappears; the reaction is now in the Marcus inverted region, and the ET rate is predicted to decrease with increasing exergonicity. This prediction was elegantly verified for thermal charge

Figure 55. Schematic of the plot of the rate of ET from a biphenyl radical anion to an acceptor **A**, as a function of driving force [179].

shift reactions in the radical anions of the rigid **D-steroid-A** dyads, shown in Figure 55, which were generated by pulse radiolysis [179]. The driving force ($-\Delta G_{et}$) for the reaction was adjusted by changing the acceptor. It was found that, in qualitative agreement with classical Marcus theory, the ET rate increased with increasing exergonicity, peaked and then fell off. This work nicely illustrates another use for rigid covalently linked dyads: the main purpose of the bridge in this series of experiments was to hold the donor and acceptor groups at a constant distance from each other.

1.17.1 Through-Bond-Mediated Electronic Energy Transfer

The transfer of excitation energy from a locally excited donor chromophore to an acceptor, resulting in the formation of the electronically excited acceptor state, is known as electronic energy transfer (EET). There are two basic EET mechanisms,

a Förster Mechanism

b Exchange Mechanism (Dexter)

Figure 56. Two principal mechanisms of excitation energy transfer (EET). (a) The Förster dipole–dipole mechanism, in which the active electrons, ① and ②, remain, respectively, on **D** and **A** throughout the process. (b) In the (Dexter) exchange mechanism, electrons ① and ② exchange locations.

namely the Förster and the Dexter (exchange) mechanisms. In the Förster mechanism (Figure 56a), EET takes place through the interaction of the oscillating dipole of the excited donor with that of the acceptor. This dipole–dipole interaction is long-range, and the rates of EET by the Förster mechanism decay inversely with the sixth power of the interchromophore separation. Note that because electrons one and two (Figure 56a) do not exchange their locations during the EET process, there is no dependence of EET dynamics on the donor–acceptor orbital overlap in the Förster mechanism.

In the exchange mechanism (Figure 56b), the two electrons exchange orbitals and so the EET dynamics now depend on inter-orbital overlap and therefore should display an exponential decay with distance. In fact, the exchange mechanism may

Figure 57. (a) Analysis of the exchange mechanism for EET in terms of two-electron transfer processes, one involving ET in the corresponding anion (center) and the other involving hole transfer (HT) in the corresponding cation (right-hand side). (b) The dyads that were used to test experimentally the relationship $k_{eet} \sim k_{et}k_{ht}$ for a triplet-triplet EET process [180]. *D is the triplet-excited state of benzophenoyl.

be regarded as a double ET process, one electron moving from the donor LUMO to the acceptor LUMO and the other from the acceptor HOMO to the donor HOMO. This important insight is illustrated in Figure 57a, from which it should be clear that the damping factor, β_{eet} , for EET occurring by an exchange mechanism is approximately equal to the sum of the damping factors for two separate ET processes, β_{et} for electron transfer in the radical anion, and β_{ht} for hole transfer in the radical cation. This prediction has been confirmed by correlating the rates of triplet-triplet EET with those for ET and HT for the systems shown in Figure 57b [180].

Although the exchange mechanism was originally formulated in terms of direct orbital overlap between the donor and acceptor chromophores, it is clear that it can be extended to cover the case of TB-mediated EET. This is because TB coupling provides a mechanism for spatially extending the active orbitals of the two chromophores into the intervening medium, thereby facilitating interchromophore orbital overlap. TB-mediated EET has been explored using the rigid norbornylogous systems **82(n)**–**84(n)** (Figure 58) [181, 182].

The experiments involved measuring the rates of singlet-singlet EET from the first excited singlet state of DMN to the ketone or dione chromophore. The distance dependence of the EET rates in **82(n)** follows an exponential decay, rather than an inverse sixth-power law, thereby confirming that an exchange mechanism and not a

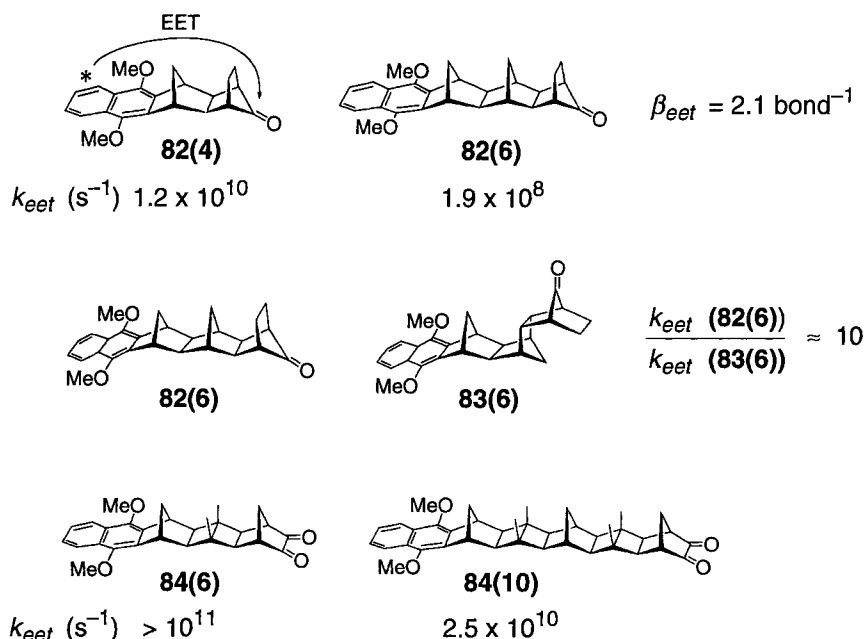

Figure 58. Rate data for singlet–singlet EET between locally excited DMN donor and carbonyl or dione acceptor in various norbornylogous systems [181].

Förster mechanism is operating in these systems [181]. The magnitude of β_{eet} was found to be about 2.1 per bond and is about double that found for photoinduced charge separation in the structurally related **DMN–B–DCV** systems **23(n)** (vide supra). This relationship agrees with the postulate that β_{eet} is the sum of damping factors for two separate ET processes. Consistent with the TB-mediated EET mechanism was the finding that singlet–singlet EET occurs about 10 times more rapidly in the all-*trans* system **82(6)** than in the “kinked” system **83(6)** [181].

How rapidly can TB-mediated EET be propagated? Considering that the rate of TB-mediated EET falls off much more rapidly than that for a single ET process, it is not surprising that most TB-mediated EET processes are insignificant for interchromophore separations exceeding 10 Å. However, there are exceptions, the most dramatic of which are provided by the series **84(n)**. Thus, the rate of singlet–singlet EET for the 10-bond system **84(10)** is an enormous $2.5 \times 10^{10} \text{ s}^{-1}$ and that for **84(6)** is too fast to be measured on a picosecond time scale [182]. The EET rate for **84(10)** is two orders of magnitude larger than that measured for the 6-bond system, **82(6)**, and six orders of magnitude faster than that predicted for the 10-bond system **82(10)**.

Just why TB-mediated EET takes place so rapidly in **84(10)** is currently a mystery, but this example certainly underscores the importance of the through-bond mechanism in mediating not only ET, but also EET processes.

1.18 Electron Transfer Mediated by Solvent Molecules

That electron transfer may be facilitated by a TB or superexchange mechanism raises the possibility that solvent molecules may also mediate ET. Presumably, the electronic coupling through solvent will not be as strong as that through a covalently linked bridge because the solvent molecules are further apart, both from each other and from the chromophores. In addition, the solvent molecules are tumbling about, and this will lead to an electronic coupling whose magnitude is less than that resulting from freezing the solvent molecules in the optimal configuration. An indication that ET could be effectively mediated by saturated hydrocarbon solvents came from early photoelectron spectroscopic and ESR studies on U-shaped dienes such as **85** (Figure 59) [15, 183, 184]. These studies revealed a remarkably large π -splitting energy of 0.52 eV for **85** which could only be explained in terms of substantial interactions between the π MOs of the double bonds and the pseudo- π orbitals of the central methano bridge (Figure 59, inset). Calculations predicted a large π -splitting of 0.32 eV for the molecular sandwich **86** which models electronic coupling between the double bonds and a methane “solvent” molecule. Given that a coupling of only 0.003 eV is sufficient to accelerate long-range ET [2], a predicted split of 0.32 eV for **86** is amazing and suggests that solvent-mediated ET should be an important process, although not as dramatic as that suggested by the idealized solvent-substrate configuration shown by **86**.

Efforts have been made to determine the importance of solvent-mediated ET in intermolecular electron transfer processes in rigid matrices [4, 5] and also in liquid solution [185, 186]. For example, the distance dependence of intermolecular ET dynamics in glassy matrices indicate that solvent-mediated ET is significant. The value of $\beta = 1.2 \text{ \AA}^{-1}$ was established for electron transfer occurring in a methyl-tetrahydrofuran matrix at 77 K under optimal driving force conditions [4]. This value is substantially smaller than that predicted for a through-space mechanism ($\beta \approx 3.0 \text{ \AA}^{-1}$), and is not much larger than that measured for ET mediated by a through-saturated-bonds mechanism ($\beta \approx 0.85 \text{ \AA}^{-1}$). Although important, the kinetic data for ET in glasses are averaged over a broad range of solute–solvent ori-

Figure 60. (a) A U-shaped dyad **87** [187]. The distance between the **DMAn** and **DCV** chromophores is 10.3 Å (HF/3-21G). (b) UHF/3-21G Gas-phase-optimized geometry of the CS state of **87** [202].

entations, and it would be desirable to investigate solvent-mediated ET under more controlled conditions where solute–solvent orientation and distance are more precisely known.

Experimental progress is being made in this direction through the synthesis of rigid U-shaped systems based on the norbornylogous bridge, representative of which are **87–91** (Figures 60–63). In these systems, the terminal chromophores face each other across a “rigid” cavity created by a norbornylogous bridge. The length and configuration of the connecting bridge are designed to minimize TB-mediated ET through the bridge, while encouraging solvent-mediated ET to occur by providing a cavity within which a certain number of solvent molecules are present (in a dynamic sense).

The dyad **87** possesses a cavity c. 10 Å wide which is sufficiently large to accommodate a solvent molecule, such as benzonitrile (Figure 60) [187]. Such a molecule

Figure 61. The *syn*- and *anti*-triads **88–90**. Geometries were optimized at the HF/3-21G level [192, 193].

would be able to provide a coupling pathway for mediating photoinduced charge separation between the locally excited singlet state of the dimethoxyanthracene (**DMA**) donor and the **DCV** acceptor. Estimated values of the electronic coupling, V_{el} , for photoinduced charge separation in **87** in various solvents were extracted from the rate data. For benzonitrile solvent, $V_{el} = 14 \text{ cm}^{-1}$, whereas for acetonitrile, $V_{el} < 2 \text{ cm}^{-1}$. These data were interpreted in terms of solvent-mediated ET using the following argument. Because photoinduced charge separation in **87** involves the LUMOs of the two chromophores, the strongest coupling with the solvent molecule will occur with the latter's LUMO rather than the HOMO. Consequently, the magnitude of V_{el} for solvent-mediated charge separation in **87** should increase with increasing electron affinity of the solvent molecule, and this is in accord with observation since the electron affinity of benzonitrile is greater than that of acetonitrile [187]. Photoinduced charge separation studies on a 9-bond **DMA**-**9-DCV** analogue of the 11-bond dyad **87**, which possesses a smaller cavity size of 7.1 \AA , likewise revealed evidence of significant through-solvent-mediated ET in electronegative solvents [188–191].

Figure 62. (a) Two trichromophoric systems used for investigating through-solvent-mediated charge recombination processes. (b) Profiles of the (U)HF/3-21G gas-phase structures of the CS state (left) and ground state (right) of an analogue of *syn*-88 in which the dimethylaniline donor is replaced by 1,4-dimethoxybenzene (DMB).

The series of rigid *syn* and *anti* triads **88–90** (Figure 61) provide useful models for investigating aspects of long-range photoinduced charge separation and subsequent dark charge recombination processes [192, 193]. These systems possess a **DMN** primary donor covalently linked to a **DCV** acceptor by an 8-bond norbornylogous bridge and to a dimethylaniline (**An**) secondary donor by a 4-, 6-, or 8-bond bridge. The *syn* isomers possess a U-shaped cavity, across which the **An** and **DCV** chromophores face each other, which is absent in the *anti* isomers.

The primary motive behind the synthesis of this series was to produce giant CS states $^+\text{An-DMN-DCV}^-$, in which the charge separation occurs over large distances, comparable to than for **23(8)**, but with much greater quantum yield than for the latter (which is $\approx 30\%$). Giant CS states are useful because increasing the distance between the charges in the CS state leads to greater longevity of that state to unwanted charge recombination. It was anticipated that the overall ET process would take place in two consecutive steps, i.e., ET from locally excited **DMN** to **DCV**, to give $\text{An-}^+\text{DMN-DCV}^-$, followed by hole transfer from **DMN** to **An** to give the final giant CS state $^+\text{An-DMN-DCV}^-$. There are many examples of the successful use of covalently linked multichromophoric systems for effecting photoinduced charge separation over large distances with high quantum yields [11, 12,

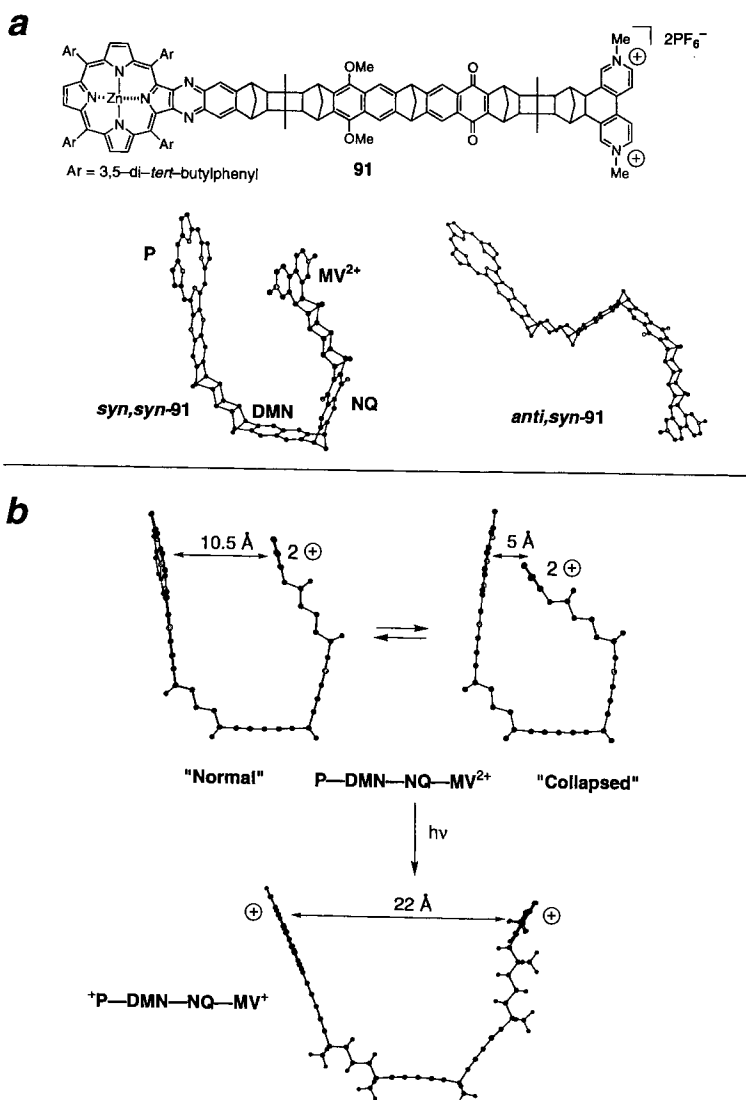

Figure 63. (a) Two tetrachromophoric systems **91**. (b) Profiles of the (U)HF/3-21G gas-phase structures for the "collapsed" ground state and giant CS state of *syn,syn*-**91**. The "normal" ground-state structure was located using the AM1 semi-empirical method.

178, 194–197], and they will be discussed in more detail Volume III, Part 2, in Chapter 2 of this Handbook. The multichromophore strategy obviously drew its inspiration from the ET cascade which takes place in the photosynthetic reaction center (see Figure 37).

Efficient photoinduced charge separation, to generate the giant CS state, was found to occur in all systems **88–90** in solvents that were sufficiently polar to stabilize the giant CS state over the “shorter” CS state $\text{An}^+\text{DMN-DCV}^-$ [198–200]. For the *syn* isomers, this process occurred even in nonpolar alkane solvents, whereas the *anti* isomers required more polar solvents because of the greater separation between the **An** and **DCV** chromophores in the latter isomers, compared to the corresponding *syn* isomers (cf. *syn-88* and *anti-88*; Figure 62a).

Although the formation of the giant CS states from **88–90** could be achieved, the lifetimes of the CS states for the *syn* isomers were amazingly short, compared to those for the respective *anti* isomers. For example, the lifetime of the giant CS state of *syn-88* is only 0.1 ns, compared to 73 ns for the *anti* isomer (in butyl ether) [201].

Solvent-mediated charge recombination taking place within the U-shaped cavity of *syn-88* could explain this result, but there is a problem with this explanation in that the CR rates are rapid, even in saturated solvents such as decalin, which have very high-lying LUMOs. Electronic coupling of the donor and acceptor LUMOs to this type of solvent molecule should, therefore, be weak and it will be further weakened by the large cavity size in *syn-88* (15 Å) which would require coupling through at least two solvent molecules.

A plausible solution to this dilemma has been found. Gas-phase ab initio MO calculations were carried out on the ground and CS states of an analogue of *syn-88*, in which 1,4-dimethoxybenzene (**DMB**) replaces the **An** chromophore (Figure 62b). Whereas the terminal chromophores in the optimized ground state structure of *syn-88* are about 15 Å apart, this separation is predicted to be only about 4.3 Å in the giant CS state $^+\text{DMB-DMN-DCV}^-$ [202]!. This large contraction in the inter-terminal separation, upon creation of the CS state is the result of electrostatic attractions between the oppositely charged terminal chromophores. The contraction is achieved by out-of-plane bending of the aromatic rings and the **DCV** radical anion and energetically is not very costly. Although these calculations refer to the gas phase, such geometric distortions should also occur in solvents of low dielectric constant, such as decalin. It is noteworthy that the small inter-terminal separation in the CS state of *syn-88* might actually enable *direct* through-space-mediated charge recombination to occur, thereby nicely explaining why CR in this molecule is so fast in weakly polar solvents of low electron affinity.

The photophysical results for the giant porphyrin–dimethoxynaphthalene–naphthoquinone–viologen tetrad, **P-DMN-NQ-MV²⁺**, **91** (Figure 63), complement those obtained for **88** [203]. Photoinduced charge separation, to form the giant CS state, $^+\text{P-DMN-NQ-MV}^+$, readily occurs in the *syn,syn* isomer, but not in the *anti,syn* isomer. This result immediately informs one that the charge separation process is not occurring through the bridge in *syn,syn-91* because if it did, then photoinduced charge separation should also be observed in the *anti,syn* isomer, since the bridges in the two systems are identical in terms of length and constitution. As observed for the charge recombination behavior for *syn-88*, the rate of photoinduced charge separation in *syn,syn-91* appears to be insensitive to solvent electron affinity. Another puzzle was the finding that the giant CS state is quite long-lived,

500 ns, which stands in marked contrast to the very short lifetime of c. 0.1 ns for the CS state of **syn-88** [203].

The conundrum may be explained by the operation of electrostatically induced geometric distortion in *both* ground and giant CS states of **syn, syn-91**. Gas-phase *ab initio* MO calculations indicate that there is an electrostatic attraction between the zinc porphyrin and the viologen dication in the ground state of **syn, syn-91** and that this results in a “collapsed” conformer, in which the porphyrin and viologen groups are only about 5 Å apart [204]. This “collapsed” structure is largely brought about by out-of-plane bending of the central pair of naphthalene rings. AM1 calculations suggest the presence of another, higher-energy conformation in which the termini are at the “normal” separation of c. 10 Å, corresponding to a fully relaxed bridge. Perhaps the “collapsed” and “normal” conformations are in rapid equilibrium. Photoinduced charge separation in the “collapsed” conformation could take place by a direct through-space mechanism without requiring electronic participation of the solvent. This would explain the solvent independence of the rate of photoinduced charge-separation observed for **syn, syn-91**. Because of the large inter-terminal separation of 10.5 Å in the “normal” conformer of **syn, syn-91**, charge separation in this conformer may be too slow to compete with unproductive decay of the locally excited porphyrin moiety.

Gas-phase geometry optimization of the giant CS state $^+P\text{-DMN-NQ-MV}^+$ offers an explanation for its very long lifetime. In this species, the terminal chromophores, both being positively charged, repel each other. As a result, the inter-terminal separation increases markedly, to about 22 Å (Figure 63b). Both through-space- and through-solvent-mediated charge recombination in $^+P\text{-DMN-NQ-MV}^+$ possessing this geometry would be unfavorable, and this would explain its long lifetime (TB-mediated CR is likewise unfavorable considering that the electronic coupling between the porphyrin and viologen chromophores must extend over 23 bonds of the bridge).

Gas-phase calculations on the CS state of **87** also predict a large change in the cavity size, from 10 Å in the ground state, to only about 4.2 Å in the CS state (Figure 60b), and that this is mainly caused by out-of-plane bending of both **DCV** and **DMA**n groups [202]. Similar geometric distortions are predicted for other U-shaped dyads in their CS states.

The predicted geometry changes that accompany charge separation in **87-91** are further examples of the harpooning mechanism [205] which is known to occur in semiflexible systems in nonpolar solvents [206, 207] and in the gas phase [57]. A typical harpooning reaction is exemplified by piperidine-based dyads such as **92** (Figure 64): Long-range photoinduced ET, from the aniline donor to the locally excited cyanonaphthalene acceptor, takes place in the chair conformation, to generate the extended CS state **93** which then undergoes an electrostatically driven conformational change (“harpooning”) into a compact (boat) exciplex-like species **94**.

In summary, solvent-mediated ET studies are proving a challenge. The prediction that “rigid” U-shaped systems undergo large structural distortions in their CS states, particularly in low-dielectric solvents, raises issues of interpretation of the data that are yet to be resolved satisfactorily.

Figure 64. An example of electrostatically driven folding ("harpooning") involving ring inversion [206].

1.19 Epilogue

The past 15 years have witnessed remarkable progress in the understanding of the character of long-range ET processes, and this has been achieved—in no small part—by the study of ET in covalently linked multichromophoric systems. Through the elegant combination of synthesis, photophysical measurements and computational quantum chemical calculations, the scope and significance of superexchange-mediated ET have been delineated. For example, it is now known that ET mediated by saturated hydrocarbon bridges can take place rapidly over distances exceeding 12 Å, and that the ET dynamics may be modulated in a predictable manner, for example by changing the bridge configuration, by orbital symmetry constraints and by the presence of strong electric fields.

These significant findings form the basis of a set of design principles for the construction of molecular photovoltaic cells and other nanoscale electronic devices in which the control of both the rate and directionality of ET processes is an essential requirement. The successful construction of an artificial light-driven proton pump, based on principles of long-range ET processes illustrates the promise of this approach [197].

Of course, it is impracticable to synthesize nanoscale devices based solely on covalently linked bridged systems, and it is reassuring to learn that ET is also strongly

mediated by H-bonded networks and by solvent molecules, thereby opening the way for the construction of photovoltaic supramolecular assemblies.

The conditions which favor the incoherent *electron transport* mechanism, associated with molecular wire behavior, over the coherent superexchange *electron transfer* mechanism are being elucidated, mainly through studies of systems possessing covalently linked *conjugated* bridges and DNA molecules. This is an exciting, emerging area of research which lies at the heart of molecular electronics.

Recent HT studies on DNA suggest that the double helix is able to act as a hole conductor, and that its conducting ability may be fine-tuned by altering the location and density of *G* sites in the helix. These findings offer the possibility of using DNA as a charge transport device in nanoscale architecture. This is an important challenge to be met in the near future! Hopefully, this review will inspire chemists from various areas to pursue not only applications of ET processes but also those fundamental issues of ET theory that still need to be resolved [208].

Acknowledgments

Support from the Australian Research Council is gratefully acknowledged, as is the award of an ARC Senior Research Fellowship.

2 Covalently Linked Systems Containing Porphyrin Units

Devens Gust, Thomas A. Moore and Ana L. Moore

2.1 Introduction

Much of the work on energy and electron transfer in porphyrin-based covalently linked supramolecular structures falls under the general rubric of artificial photosynthesis. Mimicking the natural photosynthetic conversion of sunlight into more useful forms of energy by artificial means has been a goal of photochemistry for nearly 100 years [1]. This chapter will emphasize supramolecular structures consisting of porphyrin linked to other chromophores, electron donors, and electron acceptors. These structures demonstrate a wide variety of intramolecular electron and energy transfer processes that take place among the different components. Similar processes lie at the core of the energy conversion in photosynthesis.

Artificial photosynthesis, broadly defined, is any attempt to mimic aspects of photosynthetic energy conversion by photochemical processes in laboratory-made systems. Artificial photosynthetic constructs must include a chromophore capable of absorbing light in the visible range that at the same time can act as an energy or electron donor or acceptor. Although a variety of organic and inorganic chromophores have been investigated in this respect, porphyrins and related molecules have been used extensively. Synthetic porphyrins have been especially appealing because of their similarity to the natural chromophores, their light absorption and redox properties, their stability, their relatively easy synthetic accessibility, and the large number of structural variations that are available. The great variety of structural modifications makes it possible to engineer the chromophore in order to obtain properties such as light absorption, energy transfer ability, redox potential, electronic coupling, and photoprotection.

Artificial photosynthetic systems may be designed in order to study any aspect of the natural process, including singlet energy transfer (antenna function), photo-induced electron transfer, triplet energy transfer (photoprotection), light-driven proton transfer, the coupling of light-initiated events to the synthesis of ATP, or

other biologically relevant energy-requiring processes. In this review, we will concentrate only on systems that mimic photosynthetic photoinduced electron transfer.

This chapter will begin with a simple introduction to the basic principles underlying photoinduced electron transfer and subsequently, representative examples of molecules that display interesting electron transfer phenomena will be discussed. The work reported in the 1990s will be emphasized. However, a large body of important work has appeared previous to this time, especially during the latter half of the 1970s and the 1980s. The highlights of this early work will be presented, and the reader will be referred to earlier comprehensive reviews. The present chapter is illustrative of the many types of research currently taking place in this area, but does not intend to be comprehensive.

2.2 Basic Principles Underlying Photoinduced Electron Transfer

In this section, some basic theoretical approaches to understanding electron transfer will be reviewed. Although more complex and more quantitatively accurate theories exist (see Volume I of this handbook), a discussion of these is beyond the scope of this review. The simple theories discussed below are intended only to provide a useful framework for thinking about the photophysics and photochemistry of the porphyrin based donor–acceptor systems reviewed in this chapter.

Absorption of light by an organic chromophore results in rapid formation of the lowest excited singlet state, S_1 . As shown in Figure 1, promoting an electron from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) gives a simple, illustrative description of an electronic configuration that makes up this state. Even if the excitation process produces an excited singlet state of higher energy, S_n , relaxation to the lowest-energy excited state is generally (but not always) faster than other photophysical or photochemical processes. The first excited singlet state of a porphyrin (1P) or other chromophore may relax back to the ground state either radiatively (fluorescence), or nonradiatively (internal conversion and vibrational relaxation). It may also undergo intersystem crossing to yield the triplet state (3P), which in turn can relax by radiative (phosphorescence) or nonradiative courses.

When a suitable donor or acceptor is available, interchromophore energy or electron transfer can compete with these unimolecular processes. For example, as is evident from Figure 1, 1P has a vacancy in its HOMO, and may consequently accept an electron from a nearby donor moiety. Alternatively, 1P also has a high-energy electron in its LUMO, and may readily donate this electron to an appropriate acceptor species. In general, a molecule in its excited state is both more easily oxidized and more easily reduced than in its ground state.

Because, the lifetimes of the excited singlet states of free base porphyrins are seldom longer than ~ 10 ns, and the lifetimes of metalated porphyrin singlet states

Figure 1. Schematic diagram showing occupation of the frontier orbitals of a chromophore in the ground and first excited singlet states.

are typically even shorter, a high quantum yield for photoinduced electron transfer requires that the electron transfer process occur with a time constant of at least 1 to 0.1 ns. In most of the reactions discussed in this review, the electron transfer occurs in the nonadiabatic regime. Equation 1 has been developed to describe electron transfer rate constants (k_{et}) under these conditions [2–4].

$$k_{et} = \sqrt{(\pi/\hbar^2 \lambda k_B T)} |V|^2 \exp[-(\Delta G^\circ + \lambda)^2 / 4\lambda k_B T] \quad (1)$$

Rapid electron transfer requires optimizing the parameters in Eq. 1 that are a function of the molecular design. The pre-exponential factor includes the electronic matrix element V that describes the coupling of the reactant state with that of the product. Element V is a function of the overlap of the donor and acceptor orbitals. In addition to Planck's constant \hbar , Boltzmann's constant k_B , and the absolute temperature T , the pre-exponential factor also includes the reorganization energy for the reaction, λ . The reorganization energy is associated with the nuclear motions involved in transforming the molecule from the initial to the final state. Frequently λ is expressed as the sum of a solvent-independent term λ_i , which originates from internal molecular structural differences between the reactant and product, and λ_s , the solvent reorganization energy, which is due to differences in the orientation and polarization of solvent molecules around the (usually neutral) ground state and the (usually zwitterionic) charge-separated state. The exponential term is the Franck–Condon factor that includes the standard free energy change for the reaction, ΔG° , as well as λ .

Electron transfer as described by Eq. 1 may occur in three regimes. In the “normal” region, increasing thermodynamic driving force for electron transfer (as ΔG° becomes more negative) leads to more rapid electron transfer, as would be expected

for most chemical reactions. When $-\Delta G^\circ$ equals λ , the rate of electron transfer is maximized as a function of driving force, and electron transfer becomes activationless. Finally, when $-\Delta G^\circ > \lambda$, increasing driving force leads to a decrease in the electron transfer rate constant. This is the “inverted” region of Eq. 1. Semiclassical refinements of Eq. 1 have been found to be more appropriate for describing electron transfer rates in the “inverted” region [5, 6].

2.2.1 Electronic Coupling

The electronic coupling of the reactant state with the product state, V , is a function of the overlap of the donor and acceptor orbitals. This in turn depends on energetic, spatial, geometric, and symmetry factors. At relatively large donor–acceptor separations, it can be assumed that the relevant orbitals decay exponentially with distance. In these cases, the electron transfer rate constant will depend on this separation as per Eq. 2, where R_{DA} is the donor–acceptor separation and β is a constant that expresses the sensitivity of the

$$k_{et} = v \exp(-\beta R_{DA}) \quad (2)$$

electron transfer rate constant to distance. In most of the covalently linked electron donor–acceptor systems discussed below, electronic coupling occurs via a superexchange interaction involving the bonds of the bridge between the two moieties (see Volume III, Part 2, Chapter 1). In such cases, the dependence of the electron transfer rate constant on the number of covalent bonds joining the donor and acceptor π -electron systems is also usually well described by an exponential function.

2.2.2 Solvent Effects

Electron transfer reactions involve changes in the overall charges on the donor and acceptor moieties. The stability of charged species depends strongly on the environment. An ion is stabilized by solvent molecules that can arrange themselves so as to partially cancel its charge. Both the free energy change, ΔG° , and the reorganization energy, λ , in Eq. 1 are generally strong functions of the solvent, and therefore electron transfer rate constants are also solvent-dependent.

A simple way to model this effect is to treat the solvent as a dielectric continuum. This treatment often fails quantitatively, but is a useful qualitative framework in which to consider solvent effects. For example, the effect of solvent on the driving force for electron transfer, ΔG° , is given by Eq. 3, which is taken from the work of Weller [7]. This treatment assumes electron transfer from the first excited singlet state of a donor D to an acceptor A and

$$\Delta G^\circ = e(E_D - E_A)_r + \frac{e^2}{4\pi\epsilon_0\epsilon_s} \left[\frac{1}{2R_D} + \frac{1}{2R_A} - \frac{1}{R_{DA}} \right] - \frac{e^2}{4\pi\epsilon_0\epsilon_s^r} \left[\frac{1}{2R_D} + \frac{1}{2R_A} \right] - E_{1D} \quad (3)$$

treats the charge-separated state as two spherical ions with radii R_D and R_A separated by a distance R_{DA} and immersed in a solvent of static dielectric constant ϵ_s . The quantities E_D and E_A represent the first oxidation and reduction potentials of the donor and acceptor as measured electrochemically in a reference solvent of dielectric constant ϵ_s^r , ϵ_0 is the permittivity of free space, e is the electronic charge, and E_{1D} is the energy of the donor first excited singlet state above the ground state. This equation includes two opposing effects. As the solvent dielectric constant increases, the individual ions in the charge-separated state are stabilized by the solvent dipoles. At the same time, Coulombic stabilization of each charge by the other is decreased as the dielectric constant increases due to screening effects.

The solvent also has an effect on the reorganization energy, λ , in Eq. 1. As mentioned above, the total reorganization energy is conveniently expressed as the sum of a solvent-independent term, λ_i , which originates from internal molecular structural differences between the initial and final states, and λ_s , the solvent reorganization energy. Marcus has proposed that λ_s depends on the static (ϵ_s) and high frequency ($\epsilon_{op} = n^2$, where n is the index of refraction) dielectric constants of the solvent as shown in Eq. 4 [8, 9].

$$\lambda_s = \frac{e^2}{4\pi\epsilon_0} \left(\frac{1}{2R_D} + \frac{1}{2R_A} - \frac{1}{R_{DA}} \right) \left(\frac{1}{\epsilon_{op}} - \frac{1}{\epsilon_s} \right) \quad (4)$$

2.3 Intramolecular Photoinduced Electron Transfer in Porphyrin-Based Systems: Dyads

The reaction center of photosynthetic organisms converts excitation energy to chemical energy in the form of transmembrane charge separation. It is a molecular-sized photovoltaic device, consisting mainly of protein but also containing redox-active cofactors. The bacterial reaction center uses excitation energy to transfer an electron from an excited bacteriochlorophyll special pair across the thickness of the membrane to a quinone labeled Q_B . In the resulting charge-separated state, the electron and positively charged "hole" are spatially (and electronically) well separated, which disfavors rapid charge recombination to the ground state. The slow charge recombination process allows the organism ample time to harvest the stored energy by subsequent reactions.

The majority of the research on the photochemistry of porphyrins linked to other moieties has been in the area of photoinduced electron transfer, and the systems studied are all in some sense mimics of the photosynthetic process described above. The simplest way to prepare a system in which porphyrin excited states can act as electron donors or acceptors is to mix a porphyrin with an electron acceptor or donor in a suitable solvent. Experiments of this type have been done for years, and a good deal about porphyrin photophysics and photochemistry has been learned from them. Although these systems are easy to construct, they have serious problems for the study of photoinduced electron transfer. In solution, donor–acceptor separation and relative orientation cannot be controlled. As indicated above, electron transfer is a sensitive function of these variables. In addition, because electron transfer requires electronic orbital overlap, the donor and acceptor must collide in order for transfer to occur. As this happens via diffusion, electron transfer rates and yields are often affected or controlled by diffusion. As mentioned above, porphyrin excited singlet states typically have lifetimes of a few nanoseconds. Therefore, efficient photoinduced electron transfer must occur on a time scale shorter than this. This is difficult or impossible to achieve via diffusion. Thus, photoinduced electron transfer between freely diffusing partners is confined mainly to electron transfer from excited triplet states, which have the required long lifetimes (on the micro to the millisecond time scale).

Photoinduced electron transfer on a shorter time scale, and therefore transfer to or from excited singlet states, requires an organizational principle that constrains the donor–acceptor separation. Various approaches to such organization exist. In natural photosynthesis, for example, the protein component holds the various donor and acceptor species at precise separations and angles, and also provides the appropriate environment which assists the electron transfer. One widely used approach in synthetic systems is to employ covalent bonding networks to constrain separations and orientations. The bonds can also provide a mechanism for orbital overlap through the phenomenon of superexchange, wherein the orbitals of the intervening bonds can mix with those of the donor and acceptor, thereby increasing net donor–acceptor electronic coupling and facilitating electron transfer. This chapter focuses on porphyrin-containing species of this type.

Porphyrin-containing donor–acceptor systems have been an active area of research for over 20 years, and there is an extremely large body of literature in the area [10]. In this chapter, we exemplify the major approaches to this research, but the main focus areas are illustrated with one or two examples, and references to additional work are provided. In many cases, we illustrate concepts with molecules studied in our own laboratories simply for reasons of convenience, although a number of other studies may have been reported.

The simplest covalently linked system for studying photoinduced electron transfer consists of a porphyrin bonded to an electron acceptor or donor moiety with appropriate redox properties. Most of these studies have employed free-base, zinc, or magnesium porphyrins because the first excited singlet states of these molecules are relatively long-lived (typically 1–10 ns), so that electron transfer can compete with other decay pathways. In addition, they have relatively high fluorescence

quantum yields, and fluorescence measurements are convenient for determination of the lifetimes of the excited states. Because the majority of such porphyrins are readily oxidized, they are often linked to organic electron acceptors such as other porphyrins, quinones, aromatic imides, and fullerenes. Although, as we shall see, such two-part—or dyad—systems are not ideal for the observation of long-lived photoinduced charge separation, they are relatively easy to prepare, and their study has revealed a wide variety of interesting photochemistry.

2.3.1 Porphyrins Covalently Linked to Other Porphyrins

The first photoinduced electron transfer step of bacterial photosynthesis involves electron donation from a bacteriochlorophyll-pair excited singlet state to a nearby bacteriochlorophyll derivative. This suggests that interporphyrin photoinduced electron transfer would be a commonly observed phenomenon in synthetic systems. Surprisingly, this is not the case, in spite of the huge number of covalently linked porphyrin dyads and more complex systems that have been prepared and studied. The reason is that porphyrins and their relatives have relatively low energy excited singlet states, and the redox potentials of the most commonly prepared and studied free base porphyrins are such that photoinduced electron transfer to produce porphyrin radical anions and cations is thermodynamically unfavorable. By introducing transition metals that can undergo redox reactions, a wide range of redox potentials is made available. However, such metalation also tends to produce porphyrins with very short-lived excited states, and photoinduced electron transfer cannot compete readily with other deactivation pathways.

Still it is possible to engineer covalently linked systems in order to observe interporphyrin photoinduced electron transfer by tuning redox potentials through peripheral substitution, metalation, and change in the structure of the porphyrin core, and such transfer has been observed in many systems [11–38]. Representative examples of some of these strategies will be described below.

Adjusting redox potentials by peripheral substitution

Porphyrin dyad **1** includes a zinc porphyrin moiety, which is a good electron donor by virtue of the metal, linked to a free base porphyrin bearing three pentafluorophenyl groups, which is a good electron acceptor due to the electron-withdrawing properties of these substituents [13, 29]. Based on these factors, photoinduced electron transfer involving the first excited singlet state of either porphyrin to produce a charge-separated state is thermodynamically favorable. The absorption spectrum of **1** in dichloromethane is essentially a linear combination of the spectra of model porphyrins, indicating that the linkage does not perturb the chromophores significantly. If a solution of **1** is excited at 560 nm, where most of the light is absorbed by the zinc porphyrin moiety, and the fluorescence emission spectrum is measured, it is found that nearly all the emission is due to the free base porphyrin; the zinc

porphyrin emission is strongly quenched. The weakness of this emission is due in part to quenching of the zinc porphyrin first excited singlet state $^1\text{P}_{\text{Zn}}\text{-P}_{\text{F}}$ through singlet–singlet energy transfer to the attached free base porphyrin, yielding $\text{P}_{\text{Zn}}\text{-}^1\text{P}_{\text{F}}$. Fluorescence excitation studies show that this transfer occurs with a quantum yield of 0.77. This singlet–singlet transfer is indicated as step 1 in Figure 2.

Time-resolved fluorescence studies of **1** yield information concerning the rates of the energy transfer and other pathways for decay of the porphyrin excited singlet states. Model zinc and free base porphyrins have fluorescence lifetimes of 1.6 ns and 8.5 ns in dichloromethane, respectively. The decay of the fluorescence of **1**, however, shows two components with time constants (τ_f) of 0.082 and 2.7 ns. Decay-associated spectra show that the shorter component represents the lifetime of the zinc porphyrin first excited singlet state, whereas the longer lifetime is that of the free base porphyrin moiety. Thus, both porphyrin first excited singlet states are quenched, and an intramolecular process in addition to singlet energy transfer must be taking place. The quenching is assigned to electron transfer to form $\text{P}_{\text{Zn}}^{\bullet+}\text{-P}_{\text{F}}^{\bullet-}$. This conclusion is supported by the spectroscopic observation of a long-lived charge-separated state formed via photoinduced electron transfer in a closely related carotene–diporphyrin triad molecule (see below), and of a photogenerated charge-separated state in a related diporphyrin using transient absorption techniques on the picosecond time scale [13]. Steady-state and time-resolved fluorescence results allow calculation of the rate constants for the various pathways shown in Figure 2. As indicated above, the quantum yield of singlet–singlet energy transfer from $^1\text{P}_{\text{Zn}}\text{-P}_{\text{F}}$ to give $\text{P}_{\text{Zn}}\text{-}^1\text{P}_{\text{F}}$ is 0.77 from fluorescence steady-state measurements. This value for the quantum yield and the fluorescence lifetime of the zinc porphyrin (0.082 ns) allow the calculation of the rate constant for the energy transfer from $^1\text{P}_{\text{Zn}}\text{-P}_{\text{F}}$ to give $\text{P}_{\text{Zn}}\text{-}^1\text{P}_{\text{F}}$, k_1 , as $9.4 \times 10^9 \text{ s}^{-1}$, from the relationship $\Phi_1 = k_1 \tau_f$. As-

Figure 2. Transient states and interconversion pathways for porphyrin dyad **1**. Steps 3 and 4 include intersystem crossing to the triplet, internal conversion to the ground state, and fluorescence.

suming that the repopulation of ${}^1P_{Zn}-P_F$ via step 2 is negligible (endergonic), the rate constant for photoinduced electron transfer from the zinc porphyrin first excited singlet state to the free base porphyrin (k_6) can be obtained from Eq. 5.

$$1/\tau_f = k_1 + k_3 + k_6 \quad (5)$$

The value of k_3 may be estimated as $6.3 \times 10^8 \text{ s}^{-1}$ from the 1.6-ns fluorescence lifetime of a model zinc porphyrin which cannot undergo energy or electron transfer. Thus, by Eq. 5, k_6 is $2.2 \times 10^9 \text{ s}^{-1}$. Because the 2.7-ns component has the spectrum of the free base porphyrin, it represents the decay of $P_{Zn}-{}^1P_F$. This decay should include step 4 and the electron transfer step 5. The value of the rate constant for step 4 may be estimated as $1.2 \times 10^8 \text{ s}^{-1}$ from the 8.5-ns the singlet excited state lifetime (τ_0) measured for a model porphyrin for P_F . The electron transfer rate constant from the free base porphyrin to yield $P_{Zn}^{*+}-P_F^{*-}$, k_5 , is $2.5 \times 10^8 \text{ s}^{-1}$ from:

$$k_5 = 1/\tau_f - 1/\tau_0 \quad (6)$$

The effect of thermodynamic driving force on the rate constants for interporphyrin photoinduced electron transfer was investigated by synthesizing a series of porphyrin dyads in which the substitution pattern, and therefore the driving force, was varied, and studying photoinduced electron transfer using time-resolved fluorescence techniques [12]. In the series of dyads the thermodynamic driving force for interporphyrin photoinduced charge separation spans a range of 1.13 eV. Time-resolved fluorescence studies yielded 22 rate constants for photoinduced electron transfer in dichloromethane solution ranging from $4.1 \times 10^7 \text{ s}^{-1}$ to $5.0 \times 10^{11} \text{ s}^{-1}$. The data are consistent with the theoretical treatments of Marcus and Levich (Eq. 1), although there is no evidence for inverted behavior. In the normal region, electron transfer between free base porphyrin moieties is about four times faster than transfer involving a zinc porphyrin having the same thermodynamic driving force, based on electrochemical measurements. Photoinduced electron transfer to an excited singlet state and electron transfer from an excited singlet state have the same dependence upon free energy change. In a separate study, it was found that coordination of pyridine or related ligands to the metal atom of a zinc porphyrin-free base porphyrin dyad increases the rate of photoinduced electron transfer by increasing the driving force [29].

As noted above in the discussion of Eqs. 3 and 4, solvent can have a large effect on the rates of photoinduced electron transfer reactions through alterations of driving force and reorganization energy. Photoinduced electron transfer in four dyads consisting of electron-donating porphyrins covalently linked to electron-accepting porphyrins (P_D - P_A) has been studied in 17 solvents [24]. As with dyad **1**, excitation of either porphyrin moiety is followed by singlet-singlet energy transfer to the attached porphyrin and/or photoinduced electron transfer to yield the P_D^{*+} - $P_A^{\bullet-}$ charge-separated state. Electron transfer rate constants were determined as described above for **1**. Reasonable correlation of the electron transfer rate constants with the solvent static dielectric constant was observed using the Marcus theory of electron transfer (Eq. 1) and the Weller dielectric continuum model for the variation of thermodynamic driving force with dielectric constant (Eq. 3). Little or no improvement in the correlation was introduced by inclusion of a solvent dependence of the total reorganization energy using Eq. 4. These results differ significantly from those reported for porphyrin-quinone dyads (see below) [39–42]. The differences may be due to a reduced sensitivity to specific solvent interactions by the large, diffuse porphyrin ions, as was observed for the fullerene-based systems described below. Comparisons among the dyads suggest that inclusion of a *meso*-aryl group in the linkage joining the donor and acceptor porphyrins attenuates electron transfer rates only weakly.

Adjusting redox potentials by alteration of the π -electron system of the macrocycle

By changing the π -electron distribution in the porphyrin ring, substantial changes in redox potential may be achieved. Chlorins, for example, are used as electron donors

and acceptors in photosynthesis, and have also been incorporated into multiporphyrin units capable of displaying photoinduced electron transfer. Dyad **2**, for example, consists of a free base chlorin (CH, a reasonably good electron acceptor) linked to an octaalkyl-substituted zinc porphyrin (a good donor by virtue of zinc substitution and the peripheral substitution) [21]. The short linkage between the macrocycles forces their planes to be nearly perpendicular. In polar solvents such as butyronitrile, the energy of the $P_{Zn}^{*+}-CH^{*-}$ charge-separated state is estimated as 1.8 eV on the basis of electrochemical measurements, which is below the energies of the first excited singlet state of either cyclic tetrapyrrole. Excitation of a butyronitrile solution of **2** at 610 nm, where the chlorin absorbs most of the light, leads to formation of the $P_{Zn}^{*+}-CH^{*-}$ charge-separated state with a time constant of 4 ps. Charge recombination occurs in 43 ps. In toluene, on the other hand, the excited states are not appreciably quenched, and no charge separation is observed. Probably this is because in nonpolar solvents, the energy of $P_{Zn}^{*+}-CH^{*-}$ is pushed higher than the energy of the relevant excited states, as per Eq. 3. A modification of **2** in which both centers are metalated with zinc also demonstrates fluorescence quenching in polar solvents, but no charge-separated states were detected by transient absorption measurements. This quenching has been attributed to some degree of mixing of high-energy charge-separated states with the excited states [21].

**2**

Adjusting redox potentials by changing the central metal

The insertion into porphyrins of central metals capable of easy oxidation or reduction can shift the site of redox chemistry from the macrocycle π -electron system to the metal. While this substitution allows large changes in the redox properties of a porphyrin, it may introduce changes in the photophysics if a transition metal is employed. For example, iron (III) porphyrins are particularly good electron acceptor moieties, and have been used as components of porphyrin dyad and more complex systems that show photoinduced electron transfer behavior [11, 18, 19, 26, 31, 32, 34, 43, 44]. McLendon and coworkers used this strategy with dyad **3**, in

which a free base porphyrin is linked to an Fe(III) porphyrin via a *meso* phenyl group, and related molecules [31]. Excitation of the free base porphyrin in methanol allowed detection of photoinduced electron transfer with a rate constant of $2 \times 10^{11} \text{ s}^{-1}$ to yield a $\text{P}^{*+}\text{-P}_{\text{Fe(II)}}$ charge-shifted state.

**3**

In 1992, McLendon and coworkers reported results of a study of another series of porphyrin dyads with zinc in one porphyrin and iron in the second. These were related in structure to dyad **3**, but the number of phenyl linkers varied from one to three. These workers found an apparent value for β in Eq. 2 of 0.4 \AA^{-1} . They explained this result by a theory that attributes the drop in rate constant not to increased distance, but rather to the decrease in conjugation between the porphyrins that occurs at each phenyl ring junction due to the biphenyl twist angle of $\sim 50^\circ$. Each phenyl ring results in a drop in rate of approximately six-fold [32].

In 1990, Osuka, Maruyama, Mataga, and coworkers examined porphyrin dyad **4** and other molecules closely related to dyad **3** with different aromatic linkers joining the macrocycles [19]. When the zinc porphyrin of **4** was excited in dimethylformamide solution, $^1\text{P}_{\text{Zn}}\text{-P}_{\text{Fe(III)}}$ was produced. It decayed with a time constant of 52 ps, and the $\text{P}_{\text{Zn}}^{*+}\text{-P}_{\text{Fe(II)}}$ state was observed by transient absorption techniques. The charge-shifted state decayed in 1.6 ns. By studying photoinduced electron transfer in the entire series of molecules with different linkages, the dependence of rate constant on the separation of the porphyrins was determined. A value for β in Eq. 2 of 0.4 \AA^{-1} was obtained.

**4**

Gold porphyrins have also been exploited as electron acceptors. Dyad **5**, for example, is a V-shaped molecule consisting of a zinc tetraarylporphyrin linked to an Au(III) tetraarylporphyrin through a phenanthroline spacer [30]. Excitation of the zinc porphyrin yields $^1\text{P}_{\text{Zn}}\text{-P}_{\text{Au}}^+$, which by electron transfer decays to yield the $\text{P}_{\text{Zn}}^{\bullet+}\text{-P}_{\text{Au}}^{\bullet}$ state. This charge shift reaction has a time constant of 55 ps in butyronitrile solution. The state $\text{P}_{\text{Zn}}^{\bullet+}\text{-P}_{\text{Au}}^{\bullet}$ decays back to the ground state with a lifetime of 600 ps. Excitation of the gold porphyrin moiety yields the excited triplet state, $\text{P}_{\text{Zn}}\text{-}^3\text{P}_{\text{Au}}^+$, which decays by a combination of electron transfer from the zinc porphyrin to give $\text{P}_{\text{Zn}}^{\bullet+}\text{-P}_{\text{Au}}^{\bullet}$ and triplet energy transfer to yield $^3\text{P}_{\text{Zn}}\text{-P}_{\text{Au}}^+$. The lifetime of $\text{P}_{\text{Zn}}\text{-}^3\text{P}_{\text{Au}}^+$ is 120 ps, and that of $\text{P}_{\text{Zn}}^{\bullet+}\text{-P}_{\text{Au}}^{\bullet}$ is again 600 ps. Electron transfer occurs through the bonds of the linker joining the two porphyrin moieties, as is generally the case in covalently linked systems. It was concluded that electron transfer from the zinc porphyrin excited singlet state is mediated by the LUMO of the spacer, whereas transfer to the gold porphyrin triplet state involves the HOMO of the spacer. Charge recombination shows no preferred pathway, and may involve through-space transfer between the porphyrins, which are in relatively close proximity.

5

2.3.2 Porphyrins Covalently Linked to Quinones

The first covalently linked porphyrin-based systems for mimicry of photosynthetic electron transfer were reported in the late 1970s. These were porphyrin–quinone dyad molecules **6** and **7** [45–47]. Subsequent to these reports, a very large number of porphyrin–quinone dyads have been studied, and still work in this field continues. Connolly and Bolton reviewed the work in the 1970s and 1980s [48]. Since that

time, a number of other reviews of these and related systems have appeared [10, 43, 49–60], and the material in them complements that in this chapter.

The basic photophysical behavior of porphyrin–quinone systems is illustrated by dyad **8**, in which a naphthoquinone derivative is linked to a porphyrin via an amide bond [61]. The photophysics of this molecule has been investigated using techniques

Figure 3. Transient states and interconversion pathways for a porphyrin–quinone dyad such as **8**.

such as time-resolved fluorescence spectroscopy and time-resolved absorption spectroscopy.

The states of interest are shown in Figure 3. In **8** and most other porphyrin–quinone dyads, the electronic interaction between the porphyrin and quinone moieties is relatively weak, and the absorption spectrum is essentially the sum of the spectra of the individual chromophores, as measured for model compounds. The energy of the first excited singlet state (Figure 3) is estimated as the wavenumber average of the longest-wavelength absorption maximum and the shortest-wavelength fluorescence maximum. In the case of **8**, this is 1.97 eV. The energy above the ground state of the $P^{\bullet+}-Q^{\bullet-}$ charge-separated state resulting from photoinduced electron transfer may be estimated from the first oxidation potential of the porphyrin and first reduction potential of the quinone, measured electrochemically on the dyad itself or suitable model compounds. For **8**, this value is 1.45 eV, and ΔG° for the photoinduced electron transfer is -0.52 eV. Such estimates are most valid in polar solvents similar to those used for the electrochemical measurements. In other solvents, Eq. 3 or more sophisticated treatments may be used to correct for solvent effects.

Excitation of the porphyrin moiety of **8** in benzonitrile solution with a 9-ps pulse

of laser light at 590 nm yields the first excited singlet state, $^1\text{P-Q}$. Time-resolved fluorescence measurements report the decay of this state by an exponential process with a lifetime (τ_f) of 102 ps. As the lifetime of a model porphyrin lacking the quinone moiety is 9.3 ns, this represents a strong quenching of the porphyrin excited state. The attachment of the quinone opens up a new pathway for decay—photoinduced electron transfer to generate $\text{P}^{+\bullet}\text{-Q}^{\bullet-}$ (step 2 in Figure 3). The rate constant for step 2 can be calculated by the expression of Eq. 6, where $1/\tau_0$ corresponds to k_1 , the reciprocal of the 9.3-ns lifetime of the model porphyrin, which is the sum of the rate constants for decay of the porphyrin first excited singlet state by internal conversion, intersystem crossing, and fluorescence. Thus, $k_2 = 9.7 \times 10^9 \text{ s}^{-1}$. The quantum yield of photoinduced electron transfer is given by $\Phi_2 = k_2\tau_f$ and equals 0.99.

The $\text{P}^{+\bullet}\text{-Q}^{\bullet-}$ state can be observed by transient absorption spectroscopy because the absorption spectrum of the charge-separated state differs from that of the porphyrin first excited singlet state. Measurement of the transient absorption spectrum of a benzonitrile solution of **8** as a function of time following excitation with a 150 to 200-fs laser pulse at 590 nm allowed determination of the rate constant for decay of $\text{P}^{+\bullet}\text{-Q}^{\bullet-}$ back to the ground state (step 3 in Figure 3). The value obtained for k_3 is $5.3 \times 10^{11} \text{ s}^{-1}$ [61].

Structures **9** to **22** illustrate a few of the many porphyrin–quinone dyads in the literature. Most of these demonstrate photoinduced electron transfer behavior similar to that described for **8** [48]. A large number of such dyads have been reported since 1990 [11, 39, 40, 52, 55, 56, 62–105]. As will be illustrated below, some classes of these molecules have proven to be very useful in the study and application of photoinduced electron transfer phenomena.

Effect of electronic coupling on porphyrin–quinone electron transfer rates

By changing the nature of the donor–acceptor linkage while keeping driving force essentially constant, the effect of the electronic coupling V in Eq. 1 can be investigated [103]. Compound **9** is an example where by inserting one or two additional bicyclooctyl groups the coupling between the porphyrin and quinone, V was varied [107]. A value for β in Eq. 2 of ≥ 1.4 was determined for the bicyclooctyl group, whose insertion or removal gives rise to a 4 Å change in donor–acceptor separation. Values for β of ~ 1 are commonly observed in organic linked donor–acceptor systems where large-scale intramolecular motions are precluded [108–112].

Dyads **11** and **12** differ only in the *syn* or *anti* relationship of the phenyl groups in the porphyrin–quinone linkage. Photoinduced electron transfer in **12** is approximately twice as rapid as in the stereoisomeric **11**, and this is attributed to better orbital overlap in the spacer of **12**, giving rise to a larger coupling [113].

Another interesting example is provided by dyads **13–16** [59, 74, 91]. The simi-

larity in structures among these four molecules suggests that the Franck–Condon factors for electron transfer are similar for all four, and that differences in rates must be due to differences in coupling. However, photoinduced electron transfer in tetrahydrofuran solution is 3.4 times faster in **13** than in **15**, and 8.1 times faster in **14** than in **16**. In principle, these differences could be due to differences in the bonding patterns in the bridges (superexchange), or simply differences in direct donor–acceptor interactions through the solvent medium. The authors argue on the basis of AM1 calculations that the direct interactions are most important.

Photoinduced electron transfer in dyad **17** and related compounds has been extensively studied using optical and electron paramagnetic resonance (EPR) tech-

niques [55, 63, 75, 85, 100, 101, 104]. These results have been compared with those of theoretical calculations of V , and good agreement for variations of dihedral angle and donor-acceptor separation has been obtained.

Effect of driving force on porphyrin-quinone electron transfer rates

Dyad **9** and related molecules prepared by Dervan and coworkers are good examples for these types of studies [87, 107, 114, 115]. The phenyl and bicyclo[2.2.2]octyl linkers joining the zinc porphyrin and the quinone effectively constrain the center-to-center distance between the donor and acceptor, although rotation about the single bonds in the linkage is facile. By varying the substituents on the quinone moiety, the reduction potential of this species was altered, and consequently the thermodynamic driving force for photoinduced electron transfer was varied over a range of values from about 0.5 to 1.4 eV (depending upon the solvent). This system was used to investigate the dependence of the photoinduced electron transfer rate constant on ΔG° , and the results are interpretable in terms of Eqs. 1, 3, 4 and similar treatments. In accord with Eq. 1, when the driving force is relatively small, the photoinduced electron transfer rate constant increases with increasing driving force. At higher driving force values, when $-\Delta G^\circ$ approaches the reorganization energy λ , the rate constant tends to become relatively independent of ΔG° . Interestingly, it was not possible to confirm the existence of the inverted region for photoinduced electron transfer (Eq. 1) in these molecules. This may be because it was not possible to synthesize a dyad with sufficient thermodynamic driving force. This is a common limitation in porphyrin-based systems, in part because the excitation energy of absorbing chromophore is relatively low, and this in turn requires electron donors and acceptors that are easily oxidized or reduced.

A similar result was obtained by Osuka and coworkers with dyad **10** and related molecules in which the driving force for electron transfer was altered by quinone substitution [79, 80]. No evidence for inverted behavior in photoinduced charge separation was observed up to a driving force of ~ 1.54 eV. In the charge recombination reaction of $P_{Zn}^{++}-Q^{*-}$, a decrease in rate with increasing driving force was observed, in accord with inverted behavior in Eq. 1.

Effect of solvent and temperature on porphyrin-quinone electron transfer rates

As mentioned before, electron transfer rate constants are in general strongly dependent upon solvent, as increasing the solvent polarity increases both the driving force (Eq. 3) and the reorganization energy (Eq. 4). Some of the most extensive investigations of solvent dependence have been reported by Bolton and coworkers, who have investigated photoinduced electron transfer in a porphyrin-quinone dyad in 16 different solvents [39-42]. Photoinduced electron transfer rate constants vary from $2.0 \times 10^7 \text{ s}^{-1}$ in 1,2-dimethoxyethane to $2.3 \times 10^9 \text{ s}^{-1}$ in chloroform. The results were found to correlate reasonably well with Eq. 1 when the effects of solvent on both ΔG° and λ were taken into account. The reorganization energy was estimated using Eq. 4. Agreement with theory was rather poor using Eq. 3 to estimate ΔG° , and better agreement was achieved by measuring the redox properties of the donor and acceptor moieties in each solvent, and using these to estimate ΔG° directly. Correcting ΔG° by taking into account Coulombic stabilization of the ions

in the charge-separated state also gave good correlations. This work points out the pitfalls of using equations such as Eqs. 3 and 4. These equations are easy to apply and can yield qualitative insights, but they oversimplify solvent effects by treating the solvent as a dielectric continuum. Electron transfer reactions in general are very sensitive to solvent properties and specific solvent–solute interactions are bound to be important.

Other investigations of the effect of solvent on electron transfer rate constants in porphyrin–quinone dyads have been reported [68, 80, 115, 116]. In general, the results are in qualitative agreement with expectations based on Eqs. 1, 3, and 4 or related expressions, but there are usually quantitative deviations due, at least in part, to the specific interactions mentioned above.

It is clear from Eq. 1 that in general, temperature will affect the rate of electron transfer reactions. However, lowering the temperature of a reaction mixture often has another effect that has a very large influence on transfer rate constants. As the temperature is decreased, a regime is eventually reached in which solvent molecular translational and rotational motions are slow as the solvent becomes glassy or crystalline. In this regime, the solvent molecules are no longer free to effectively solvate and stabilize the ions in a charge-separated state, or transition state leading to a charge-separated product. In Eqs. 3 and 4, this effect could be interpreted as a decrease in the solvent dielectric constant, which lowers the solvent reorganization energy, and increases the energy of a charge-separated state. In many cases, the energetics of the donor–acceptor system have been designed to maximize the fraction of photon energy stored in the charge-separated species in relatively polar solvents. Thus, when the molecule is studied in, for example, a frozen organic glass, the energy of the charge-separated state is raised. However, the energy of the photoexcited state is basically unaffected by the medium properties, and the result is that the driving force for photoinduced electron transfer is reduced to the point that formation of the charge-separated state is too slow to compete with other pathways for decay of the excited state. The process could even become endergonic. For example, as mentioned above, photoinduced electron transfer is rapid in dyad **8** in most organic solvents at ambient temperatures. However, when the molecule is dissolved in a 2-methyltetrahydrofuran glass at 77 K, no porphyrin fluorescence quenching is observed and electron transfer does not occur.

Wasielewski and coworkers have studied a series of molecules in which porphyrins are linked to quinones and similar electron acceptors, and determined that when a solvent such as 2-methyltetrahydrofuran freezes, about 0.8 eV of driving force is lost [116]. These researchers have prepared dyads with a driving force for photoinduced electron transfer greater than this value in polar solvents, and found that they are capable of displaying photoinduced electron transfer even in frozen organic glasses. This, in turn, has opened the door to low-temperature EPR studies of the charge-separated states in various donor–acceptor systems and their decay pathways [66, 99, 117].

Rigid porphyrin–quinone systems

Porphyrin-containing donor–acceptor systems have been employed to test various theoretical descriptions of electron transfer. Such studies require not only accurate

spectroscopic and electrochemical data, but also a precise knowledge of molecular structure, because electron transfer rates depend on electronic coupling interactions (Eq. 1). Interpretation of the results of these studies is simpler if the system possess a high degree of structural "rigidity," that is low conformational mobility. Some systems have come close to achieving this objective.

All of the dyads discussed above—and certainly most of those that have been prepared—feature at least one single bond in the donor–acceptor linkage about which some degree of rotation can occur. This can complicate interpretation of electron transfer rate data in several ways. It may be difficult to determine which of several likely conformations is of lowest energy, or whether several conformations may be populated under the conditions of the experiment. If interconversion of various conformers on the time scale of electron transfer is slow, multiple rate constants may be observed. If interconversion is rapid, the measured rate constants will be relevant only for the average population.

Such considerations have led to the design and synthesis of dyads with a very high degree of structural rigidity. Dyad **18** is an example where the bicyclic linkages severely restrict large-scale intramolecular motions [67, 118, 119]. Fluorescence decay studies in chloroform yield a rate constant for photoinduced electron transfer of $1.5 \times 10^{10} \text{ s}^{-1}$, which is remarkably rapid, given the large donor–acceptor separation. Clearly, the bonding network in the linkage provides the electronic coupling, via superexchange. Rapid electron transfer through rigid linkages of this general type have been observed with other donor–acceptor systems and analyzed in detail [67, 118, 120, 121] (see Volume III, Part 2, Chapter 1).

Dyads **19** and **20** also feature a very rigid bicyclic scaffold between donor and acceptor, and show some unusual properties [98, 105]. The two molecules differ significantly only in the location of the naphthoquinone carbonyl groups relative to the porphyrin macrocycle. Dyad **19**, whose quinone carbonyl groups are rela-

**19****20**

tively close to the porphyrin macrocycle, exhibits photoinduced electron transfer rate constants of $\sim 1 \times 10^{12} \text{ s}^{-1}$. The transfer rate is virtually independent of solvent dielectric constant and temperature within the range 77–295 K, which spans the glass transition of the 2-methyltetrahydrofuran solvent. Dyad **20**, which has a similar donor–acceptor linkage but whose quinone carbonyl groups are $\sim 2 \text{ \AA}$ farther from the porphyrin, features photoinduced electron transfer rate constants that decrease with decreasing solvent dielectric constant. Moreover, electron transfer in this molecule ceases at low temperatures. Photoinduced electron transfer in dyad **20** exhibits the usual dependence on free energy change and solvent reorganization observed in most porphyrin–quinone systems and interpretable in terms of Eqs. 1–4, as discussed above. The unusual behavior of **19** is reminiscent of that observed in photosynthetic reaction centers, and may be attributed at least in part to the smaller separation of the porphyrin radical cation and the quinone radical anion. Equations 3 and 4 predict that a small separation can lead to nearly barrierless electron transfer and make transfer less susceptible to effects due to changes in solvent dielectric properties and temperature. Charge recombination rates in dyads **19** and **20** are substantially slower than charge separation rates, unlike those observed with many porphyrin–quinone systems.

The ionic separation may not be the only factor giving rise to the behavior of **19**, as the photoinduced electron transfer rate constant does not change appreciably, even when the driving force is increased by $\sim 0.4 \text{ eV}$ through introduction of zinc into the porphyrin macrocycle. In this connection, very rapid photoinduced electron transfer has been observed in other zinc-containing porphyrin–quinone systems [80, 86], and photoinduced electron transfer in zinc-containing porphyrin dyads has

been found to lie on a somewhat different rate versus free energy change curve than that of their free base analogues [12]. The lack of sensitivity to environmental factors suggests that photoinduced electron transfer in **19** is controlled mainly by intramolecular vibrations. Vibrational overlap terms may play a role either in the context of radiationless transition theory, or as limiting factors in the conversion of reactant to product on a quasi-adiabatic potential surface [98, 122].

An interesting class of porphyrin–quinone systems that show photochemical behavior related to that of **19** comprises cyclophanes, where the quinone is “tethered” across the face of the porphyrin by two or more linkages containing single bonds [62, 76, 77, 86, 92–95, 123–132]. Dyads **21** and **22** are representative examples. These molecules can in principle achieve strong electronic coupling through a face-to-face arrangement of the porphyrin and quinone. Some of these systems demonstrate a very weak dependence of the rate of photoinduced electron transfer on solvent and temperature, much as is observed for **19**. For example, dyad **21**, a cyclophane system examined by Lindsey, Mauzerall and coworkers undergoes photoinduced electron transfer with rate constants about 1000 times smaller than observed for **19** [62, 125]. However, the dependence on solvent and temperature is weak. Analysis of the results is somewhat complex because the flexible linkages allow two conformers with significant populations.

A group of researchers from Heidelberg and Munich have studied an extensive series of cyclophane systems related to **22** [77, 86, 92, 94, 95, 123, 129–133]. Dyads with relatively low driving force for electron transfer in polar solvents (comparable to **19**) show relatively slow photoinduced electron transfer in nonpolar solvents, and significantly faster transfer in polar solvents. For a few molecules with large negative ΔG° values, photoinduced electron transfer occurs in about 1 ps in all solvents

**21****22**

investigated, and at low temperatures. Exact transfer rate constants are unavailable because of instrumental limitations, but it is clear that the behavior of these cyclophanes is similar in many respects to that of dyad **19**. In these cases as well, electron transfer rate constants appear to be influenced mainly by internal molecular vibrations, rather than external factors, and may be approaching the “theoretical limit” [86, 122]. Charge recombination rates in these molecules also appear to be insensitive to solvent, unlike those observed for **19** and **20**. However, this interpretation may be complicated by conformational heterogeneity arising from flexibility in the porphyrin–quinone linkage. More rigid analogues of these cyclophanes may help to resolve these questions.

2.3.3 Porphyrins Covalently Linked to Fullerenes

The dark color of C_{60} in solution in organic solvents is indicative of light absorption in the visible spectrum, and the potential for interesting photochemistry. In addition, the well-known ability of fullerenes to undergo up to six electrochemical reductions at relatively accessible potentials suggests that they might serve as electron acceptors or relays in multicomponent donor–acceptor systems. Recent advances in synthetic methodology have allowed the functionalization of fullerenes, and this in turn has opened the door to linking fullerenes to other pigments and electron donor–acceptor moieties.

We reported the first example of such a compound, porphyrin–fullerene dyad **23**, in 1994 [134, 135]. Since that paper, a number of examples of dyads consisting of fullerenes linked to porphyrins or phthalocyanines have been prepared [136, 137–159]. Some of these, such as **24**, use amide linkages related to those employed in some porphyrin–quinone systems [137, 149, 152]. In dyad **25**, the moieties are linked by an extended, rigid bridge, of the type that has been shown to facilitate rapid long-range electron transfer in other systems [146, 147]. A number of dyads feature pyrrolidine-functionalized fullerenes, as in **26** and **27** [90, 139, 145, 148].

The general photochemical behavior of such dyads will be illustrated by dyad **26** and its zinc analogue [141, 153]. The photochemical behavior of these two dyads can be discussed with reference to Figure 4, which shows the relevant states and interconversion pathways. The energies of the excited singlet states in the figure

23

were estimated from absorption and emission properties. The fullerene absorbs throughout the visible until ~ 710 nm, but the extinction coefficients are much lower than those of the porphyrin. As with the other dyads discussed above, the absorption spectra are essentially linear combinations of those of the component chromophores, and the spectra show no evidence of strong electronic interaction of the chromophores. Cyclic voltammetric studies on **26**, its zinc analogue and model compounds allow estimation of the energies of $P^{+\bullet}-C_{60}^{\bullet-}$ and $P_{Zn}^{+\bullet}-C_{60}^{\bullet-}$ as 1.58 and 1.38 eV, respectively, above the ground states in polar solvents.

Analysis of time-resolved fluorescence and absorption data for the dyads and appropriate model compounds allows calculation of rate constants for various photochemical processes. In toluene, $^1P-C_{60}$ of **26** decays by singlet–singlet energy transfer (step 1 in Figure 4, $k_1 = 4.5 \times 10^{10} \text{ s}^{-1}$) to yield $P-^1C_{60}$, which undergoes intersystem crossing to the triplet state. No photoinduced electron transfer is observed. In benzonitrile, $^1P-C_{60}$ decays by a combination of photoinduced electron transfer by step 2 ($k_2 = 1.8 \times 10^{11} \text{ s}^{-1}$) to give $P^{+\bullet}-C_{60}^{\bullet-}$ and singlet energy transfer by step 1 ($k_1 = 7.1 \times 10^{10} \text{ s}^{-1}$). The $P-^1C_{60}$ formed in this manner or by direct absorption of light decays by photoinduced electron transfer step 3 to also yield the $P^{+\bullet}-C_{60}^{\bullet-}$ state ($k_3 = 1.3 \times 10^{10} \text{ s}^{-1}$). The charge-separated state may be readily identified using transient absorption spectroscopy through the absorption of the porphyrin radical cation in the 600–700 nm region and the fullerene radical anion at about 1000 nm. The overall quantum yield of charge separation via both pathways is 0.99. The $P^{+\bullet}-C_{60}^{\bullet-}$ state decays by charge recombination to the ground state with $k_6 = 3.4 \times 10^9 \text{ s}^{-1}$.

Qualitatively, the excited singlet states of the zinc dyad decay by similar pathways. However, the rate constants are different due mostly to differences in energetics. The first excited singlet state of the zinc porphyrin moiety is higher in energy than the corresponding state of the free base dyad, and the energy of the charge-separated state is lower due to stabilization of the positive charge in the zinc porphyrin. In toluene, $^1P_{Zn}-C_{60}$ decays by singlet energy transfer to the fullerene giving $P_{Zn}-^1C_{60}$ with a quantum yield of essentially unity. The fullerene singlet state

Figure 4. Transient states and interconversion pathways for porphyrin–fullerene dyads. The solid bars represent energies for free-base porphyrin–fullerene dyad **26**, and the dashed bars represent energies for the zinc-porphyrin–fullerene dyad. Solid bars represent singlet or charge-separated states, and hollow bars stand for triplet states. The energies of the charge-separated states refer to polar solvents.

decays with a rate constant of $7.0 \times 10^8 \text{ s}^{-1}$. This rate constant is similar to that for decay of $^1\text{C}_{60}$ in model compounds, and presumably involves mainly intersystem crossing to the triplet.

In benzonitrile, $^1\text{P}_{\text{Zn}}\text{-C}_{60}$ decays in 1.9 ps by a combination of electron transfer and singlet energy transfer. If we assume that the rate constant for energy transfer step 1 in Figure 4 is approximately the same in toluene and benzonitrile ($4.9 \times 10^{10} \text{ s}^{-1}$), then the rate constant for photoinduced electron transfer step 2 is $4.8 \times 10^{11} \text{ s}^{-1}$, the quantum yield of charge separation from this state is 0.91, and the quantum yield of singlet energy transfer is 0.09. As no fluorescence emission with a lifetime longer than 1.9 ps was detected from $\text{P}_{\text{Zn}}\text{-C}_{60}$ in benzonitrile, photoinduced electron transfer from $\text{P}_{\text{Zn}}\text{-}^1\text{C}_{60}$ to give $\text{P}_{\text{Zn}}^{*\text{+}}\text{-C}_{60}^{*\text{-}}$ (step 3) must also occur with a rate constant of $\sim 5 \times 10^{11} \text{ s}^{-1}$. The $\text{P}_{\text{Zn}}^{*\text{+}}\text{-C}_{60}^{*\text{-}}$ state formed from the two pathways is produced with an overall quantum yield of essentially unity, and decays with $k_6 = 2.0 \times 10^{10} \text{ s}^{-1}$.

Imahori, Sakata and coworkers have bound porphyrin–fullerene dyad **27** to a

gold surface using the sulfide moiety, and observed photocurrents from this construct when it makes up part of a photoelectrochemical cell [148].

Porphyrin–fullerene dyad **28** and related molecules are cleverly designed ion-selective switches [143, 144]. In the absence of metal ions, the molecule exists in a relatively extended conformation, but in the presence of potassium ion, the molecule forms a crown-ether-like complex with the metal ion in which the porphyrin and fullerene interact more strongly. This increased interaction results in spectral perturbations and an enhanced quenching of the porphyrin fluorescence, which is likely due to enhanced electron or energy transfer to the fullerene.

In general, the studies of photoinduced electron transfer in porphyrin–fullerene dyads have shown that charge-separated states are produced in high yield, and have long lifetimes, relative to those of similar porphyrin–quinone systems [135, 141, 152, 153, 158]. For example, a comparison of the photochemistry of porphyrin–fullerene dyad **24** with that of the structurally related porphyrin–quinone dyad **29** shows that redox potentials and electronic coupling interactions are similar in the two compounds [152]. In tetrahydrofuran solution, photoinduced electron transfer in **24** occurs with a rate constant of $9 \times 10^9 \text{ s}^{-1}$. In **29**, the corresponding rate is $1.5 \times 10^9 \text{ s}^{-1}$, even though the driving force is larger by 0.28 eV. The most remarkable difference is in the charge recombination reaction. In **24** occurs with a rate constant of $2 \times 10^9 \text{ s}^{-1}$, whereas in porphyrin–quinone dyad **29**, the rate constant is greater than $5 \times 10^{10} \text{ s}^{-1}$. The differences in rate constants have been ascribed to a significantly smaller λ_i and λ_s for the large, diffuse fullerene radical ion

than for the quinone radical anion, where the negative charge is concentrated in the region of the oxygen atoms [152].

2.3.4 Porphyrins Covalently Linked to Carotenoid Polyenes

Carotenoid polyenes such as β -carotene and related compounds are easily oxidized, and in principle could serve as electron donors to porphyrin excited singlet states. It has been known for more than 20 years that in concentrated solutions, β -carotene quenches the fluorescence of chlorophylls, and photoinduced electron transfer has been suggested as a possible mechanism [160]. Similar quenching has been observed in porphyrin-carotene dyads [112, 161–167]. Although photoinduced electron transfer is a possible mechanism for such quenching, other possibilities such as singlet-singlet energy transfer from the porphyrin to a lower-lying carotenoid excited singlet state (which is a formally forbidden transition, not observed in absorption), and alteration of the porphyrin rate constants for fluorescence, internal conversion or intersystem crossing [165]. The dominant mechanism will depend upon the particular molecular structure.

There is one experimentally verified example of the quenching of a porphyrin first excited singlet state by photoinduced electron transfer from an attached carotenoid [166]. Carotenoporphyrin **30** features a synthetic carotenoid polyene linked to a porphyrin bearing three pentafluorophenyl groups. The electron-withdrawing nature of these fluorinated groups increases the reduction potential of the porphyrin so that there is a relatively large driving force for photoinduced electron transfer. Excitation of the porphyrin moiety of **30** in butyronitrile solution with a ~ 200 -ps laser pulse gives the porphyrin first excited singlet state, $C^{-1}P_F$, which decays with a rate constant of $1.8 \times 10^{10} \text{ s}^{-1}$ to yield the $C^{+\bullet}-P_F^{-\bullet}$ charge-separated state with a quantum yield of essentially unity. The state was identified via the strong transient absorption of the carotenoid radical cation, with a maximum at 960 nm. It decays with a lifetime of 2.9 ps. It is possible that a similar electron transfer process is responsible for the porphyrin fluorescence quenching observed in other carotenoporphyrins.

porphyrin systems, but that charge recombination is much more rapid than charge separation, making spectroscopic observation of the carotenoid radical cation difficult.

A novel noncovalent system featuring porphyrin excited singlet state quenching by carotenoids has been reported [168]. It consists of a *meso*-tetraarylporphyrin bearing cyclodextrin units on the 5- and 15-aryl groups. The two cyclodextrin units work cooperatively to bind a single β -carotene molecule, which is held so that its center is very close to the porphyrin π -electron system. Porphyrin fluorescence quenching was observed, and used to determine a binding constant for the complex.

A study of a *meso*-tetraphenylporphyrin bearing four negatively charged, bixin-based carotenoid substituents has shown that in water at pH 9, unilamellar vesicles made up of monolayer membranes are formed [169]. In the presence of guanidinium porphyrin counter ions, excitation at wavelengths absorbed by porphyrins leads to photoinduced electron transfer. Spectroscopic evidence for the bixin radical cations and porphyrin radical anions was obtained. Presumably, photoinduced electron transfer from the bixin to porphyrin first excited singlet states is involved in the formation of the radical ions.

Electron donation from a carotenoid excited singlet state to a porphyrin is energetically possible in some cases, but has not been observed. Carotenoid excited singlet states in general are not photochemically active because of their short lifetimes. The electric-dipole-allowed S_2 state, which is observed spectroscopically in absorption, has a lifetime of ~ 200 fs, and the forbidden S_1 state, which is populated by relaxation from S_2 , decays in ~ 10 ps. Thus, any electron transfer process would have to be extremely rapid, requiring a large thermodynamic driving force and relatively strong donor–acceptor electronic interactions.

2.3.5 Porphyrins Covalently Linked to Aromatic Imides

Most of the early studies of photoinduced electron transfer in porphyrin-containing supermolecules used quinones as electron acceptors. However, other electron-accepting moieties offer significant advantages in some cases. In 1985, Cowan and

31 $n = 2$

32 $n = 3$

coworkers [170, 171] reported the use of an aromatic imide as an electron acceptor in cyclophane dyads **31**, **32** and related dyads. Since that time, a number of other researchers have employed such acceptors, and they have proven useful in dyad, triad, and more complex devices [14, 15, 56, 173–185]. Imide acceptors can be more chemically robust than quinones, and can be linked to other molecules in ways that limit conformational mobility. In some cases, their radical anions have characteristic absorption spectra that allow relatively easy spectroscopic detection.

Beddard, Cowan, Sanders and coworkers have used porphyrin–imide (P-Im) dyads **31**, **32** and related molecules to make an extensive study of the effect of driving force, solvent, electronic coupling, metalation state, coordination state, conformation, and temperature on electron transfer rate constants [171]. Rate constant data were obtained using transient fluorescence and absorption techniques. As one might expect, based on the chemistry of the porphyrin–quinone systems discussed above, excitation of the porphyrin moiety yields $^1\text{P-Im}$, which decays by electron transfer to give the $\text{P}^{+\bullet}\text{-Im}^{\bullet-}$ charge-separated state which ultimately recombines to the ground state. The results are in general agreement with the predictions of theoretical expectations as outlined at the beginning of this chapter. For example, electron transfer rate constants as a function of thermodynamic driving force are in accord with quantum mechanical extensions of Eq. 1, and inverted behavior is observed for charge recombination reactions. With long bridging groups in these cyclophanes, it was found that the pyromellitimide acceptor was bound to the central metal in the case of metalated porphyrins. This binding was disrupted upon addition of pyridine, which binds strongly to the metal, and the result is a reduction in the electron transfer rate constant. Thus, the pyridine may be used to switch electron transfer off.

An interesting phenomenon has been observed in porphyrin–imide dyad **33** and

related compounds [186]. Excitation of the porphyrin moiety of **33** in benzene leads to moderately rapid photoinduced electron transfer to the imide, and a resultant shortening of the fluorescence lifetime of $^1\text{P}_{\text{Zn}}\text{-Im}$ from 1.56 ns to 1.18 ns. The charge-separated state was detected by transient absorption spectroscopy, and has a lifetime of 40 ns. Addition of five equivalents of tetra-*n*-butylammonium fluoride resulted in coordination of fluoride ion to the boronate ester in the bridge between the porphyrin and imide, and this in turn led to a return of the fluorescence lifetime of $^1\text{P}_{\text{Zn}}\text{-Im}$ to 1.56 ns. Thus, coordination of fluoride evidently prevents electron transfer quenching of the porphyrin first excited singlet state. The reasons for this effect are not known, but may involve either the presence of the negative charge (which increases the energy of $\text{Im}^{\bullet-}$ via an electrostatic effect), or changes in electronic coupling due to hybridization changes at boron. The effect might be useful in a switch or sensor application.

2.3.6 Porphyrins Covalently Linked to Viologens

Viologen derivatives are attractive as electron-accepting units for porphyrin-containing dyads and more complex donor–acceptor systems because they are easily reduced, easily linked to other molecules through alkylation of the nitrogen atoms of precursors, and can impart a degree of solubility in polar solvents due to their charged nature. In addition, the viologen radical monocation absorbs in the visible spectrum, and can be used as a convenient way to monitor charge separation. As a result, a number of covalently linked porphyrin–viologen systems have been reported [126, 187–205]. In general, excitation of a porphyrin–viologen dyad yields the porphyrin first excited singlet state, which can either donate an electron to the viologen to form a charge-transfer state, or undergo intersystem crossing to yield the porphyrin triplet state. Because the viologen moiety is easily reduced, the porphyrin triplet state may also act as an electron donor.

An example of such a system is dyad **34**, consisting of a zinc porphyrin (P_{Zn}) linked to a viologen-like moiety, pyridylpyridinium (V^+), which is also a reasonably good electron acceptor (−0.71 V versus SCE) [189]. Excitation of the porphyrin yields $^1\text{P}_{\text{Zn}}\text{-V}^+$, which decays by photoinduced electron transfer to give $\text{P}_{\text{Zn}}^{\bullet+}\text{-V}^{\bullet}$.

**34**

with a rate constant of $3.8 \times 10^9 \text{ s}^{-1}$, as derived from time-resolved fluorescence studies. In the free base analogue, the corresponding rate constant is $7.7 \times 10^9 \text{ s}^{-1}$.

Magnetic field effects on charge recombination reactions in porphyrin–viologen systems have been observed in solution and in Langmuir–Blodgett monolayers [190, 201, 202]. Photovoltaic effects have also been observed in such films, and these have been used to initiate hydrogen evolution from platinized films [193, 195].

2.4 Intramolecular Photoinduced Electron Transfer in Porphyrin-Based Systems: Triads

As illustrated above, studies of porphyrin–acceptor dyads have allowed investigation of the basic parameters influencing the rates and yields of electron transfer reactions in covalently linked systems with relatively low-energy chromophores that absorb visible light. Although most of these studies have been carried out in solution, the results are still useful for helping understand electron transfer in photosynthetic reaction centers. Indeed, several of the systems discussed above are able to mimic well some of the key features of photosynthesis, such as absorption of visible light, and photoinduced electron transfer reactions that occur in high yield to give energetic charge-separated states. Like natural reaction centers, some of the porphyrin–quinone systems even function at low temperatures. However, all of these dyads also demonstrate rapid charge recombination to the ground state. The $\text{P}^{+\bullet}\text{Q}^{-\bullet}$ state of **8** in benzonitrile, for example, decays in less than 2 ps. This rapid decay, which is not observed in photosynthetic reaction centers, severely limits any possibility of exploiting the chemical potential energy of the charge-separated state in order to carry out redox chemical reactions, charge injection into electrical circuits, etc.

The source of the problem lies in the requirement that photoinduced electron transfer be very rapid in order to compete with decay of excited states by the usual photophysical processes. Rapid transfer requires significant electronic coupling between the initial and final states (Eq. 1), and such coupling nearly always results in

a degree of coupling for the charge-recombination reaction that leads to very rapid collapse of the charge-separated state. In principle, charge recombination can be slowed by energetic considerations. If the thermodynamic driving force for charge separation from the porphyrin first excited singlet state is relatively small, then the driving force for recombination to the ground state will be relatively large, and Eq. 1 predicts that this will slow down the reaction (inverted region). This phenomenon is evident in some of the porphyrin–quinone systems discussed above. However, the effect is relatively small, and $P^{*+}\text{-}Q^{\bullet-}$ states typically recombine in picoseconds to hundreds of picoseconds.

A much more successful solution to this problem is employed by reaction centers. Secondary electron acceptors are employed so that the initially formed radical ions are rapidly separated spatially and electronically by subsequent electron transfer reactions. Each step in this sequence of electron transfers is short-range, rapid and efficient, but the net result is a weakly coupled biradical with a long lifetime. Using this strategy, reaction centers can produce a very long-lived, highly energetic charge-separated states with a quantum yield approaching unity. There is some energetic price paid for this result, as each step in the electron-transfer cascade must be sufficiently exergonic to both occur rapidly and retard the reverse reaction, which could lead to charge recombination.

2.4.1 Triads with Porphyrin–Quinone Components

In the early 1980s this biomimetic strategy was first employed in photosynthetic model systems. Carotenoid–porphyrin–quinone triad **35**, which was reported in 1983, includes a typical porphyrin–quinone and incorporates a carotenoid polyene as a secondary electron donor [206, 207]. The photochemistry of this molecule, as determined using a variety of spectroscopic techniques, is illustrated in Figure 5. Excitation of the porphyrin moiety of this triad in benzonitrile solution is followed by photoinduced electron transfer to the porphyrin to yield $C\text{-}P^{*+}\text{-}Q^{\bullet-}$ (step 2 in Figure 5) with a rate constant k_2 of $2 \times 10^9 \text{ s}^{-1}$ [208]. The quantum yield of this state is essentially unity, as photoinduced electron transfer is much more rapid than decay of $C\text{-}^1P\text{-}Q$ by other pathways (step 1). As with other porphyrin–quinone dyads, for example **8**, this state recombines rapidly to the ground state by step 3 ($k_3 = 6 \times 10^{11} \text{ s}^{-1}$). However, competing with charge recombination is electron donation from the carotenoid (which is more easily oxidized than the porphyrin by $\sim 0.30 \text{ V}$). This process (step 4 in Figure 5), yields $C^{*+}\text{-}P\text{-}Q^{\bullet-}$ with $k_4 = 1 \times 10^{11} \text{ s}^{-1}$. The final $C^{*+}\text{-}P\text{-}Q^{\bullet-}$ state is formed with an overall quantum yield of 0.13, and has a lifetime of 340 ns in benzonitrile. The multistep electron transfer pathway in **35** increases the lifetime of the charge separation by a factor of $\sim 10^5$. This is accomplished by greatly reducing the electronic coupling between the radical ions that now are separated by the neutral porphyrin moiety. The two-step sequence still demonstrates a respectable yield of the final charge-separated state because the photoinduced electron transfer step is much more rapid than decay of the excited state by other pathways, and the rate of the second electron transfer step is comparable to that of charge recombination of $C\text{-}P^{*+}\text{-}Q^{\bullet-}$.

Figure 5. Transient states and interconversion pathways for carotenoporphyrin-quinone triad **35**.

The $C^{\cdot+}\text{-P-Q}^{\cdot-}$ state in triads such as **35** eventually recombines to the ground state, unless it is harvested by subsequent reactions. The simplest possible recombination pathway involves electron transfer from the quinone radical anion directly to the carotenoid radical cation. However, this pathway can be very slow, even if thermodynamics are very favorable, because of the weak electronic coupling between the radical ions. In some cases, charge recombination has been found to fol-

low a two-step mechanism. Slow, endergonic electron transfer from the porphyrin back to the carotenoid is followed by rapid recombination of the resulting $C-P^{++}-Q^{\bullet-}$ intermediate [209]. In other systems, both direct and two-step recombination are seen, whereas other triads recombine only by the direct mechanism [172].

In triad **35**, the initial $C-P^{++}-Q^{\bullet-}$ species is formed with a quantum yield of essentially unity. However, the final $C^{++}-P-Q^{\bullet-}$ state is generated with a quantum yield of only 0.13 in benzonitrile and 0.04 in dichloromethane. The decrease in quantum yield for the final state is due to electron transfer from the carotenoid to the porphyrin radical cation (step 4 in Figure 5) that is not rapid enough to compete successfully with charge recombination to the ground state (step 3). Equation 1 suggests that one way to improve the quantum yield is to fine-tune the thermodynamics of the system in order to enhance the rate of step 4, and ideally reduce the rate of step 3. Triad **36** was designed to investigate this strategy [210]. Replacing the tolyl substituents on the porphyrin macrocycle of **35** with pentafluorophenyl substituents increases the oxidation potential of the porphyrin by ~ 200 mV. Excitation of the porphyrin moiety of **36** in dichloromethane solution is followed by photoinduced electron transfer to the quinone to yield an intermediate $C-P^{++}-Q^{\bullet-}$ state which evolves into a final $C^{++}-P-Q^{\bullet-}$ species with an overall quantum yield of 0.30 and a lifetime of 455 ns. This significant increase over the quantum yield of 0.04 observed for **35** in the same solvent is attributed for the most part to the 200 meV increase in energy of the intermediate $C-P^{++}-Q^{\bullet-}$ state. This increase in energy decreases the driving force for the photoinduced electron transfer step 2 (see Figure 5), and thus reduces the quantum yield of this first step from 0.97 in **35** to 0.41 in **36**, according to Eq. 1. However, it also increases the rate of carotenoid-to-porphyrin electron transfer step 4, and this enhances competition of this step with charge recombination. Additionally, charge recombination by step 3 is strongly exergonic, and lies in the inverted region of Eq. 1. Thus, raising the energy of $C-P^{++}-Q^{\bullet-}$ increases the driving force for this step, and this leads to a decrease in the rate constant for charge recombination. The result is a substantially increased overall yield of the final $C^{++}-P-Q^{\bullet-}$ state.

A second example of multistep electron transfer in a model photosynthetic system also appeared in 1983 [211]. Triad **37** consists of an etioporphyrin electron photo-

donor linked to a diquinone ensemble. The distal quinone is the most easily reduced. Thus, this molecule has an engineered gradient of redox potential. Excitation of the porphyrin leads to the formation of a $P^{*+}-Q-Q^{\bullet-}$ charge-separated state, which most likely is formed by a two-step electron transfer sequence involving an intermediate $P^{*+}-Q^{\bullet-}-Q$ species. This electron transfer sequence is similar to that of photosynthetic reaction centers, where the primary donor chlorophyll initiates a chain of transfers to acceptors of increasing reduction potential. The lifetime of $P^{*+}-Q-Q^{\bullet-}$ is ~ 300 ps in benzene, which is only moderately longer than that of a related $P^{*+}-Q^{\bullet-}$ model dyad (130 ps) [211]. It has been proposed that this short lifetime is a consequence of the relatively flexible linkages joining the donor and acceptor species [212]. Internal rotations about these linkages permit the radical ions to approach one another, and this leads to sufficient electronic coupling so that charge recombination is relatively rapid. This is precluded in triad **35** because of the relatively rigid, short linkages between the various moieties, which feature amide bonds with partial double bond character.

Another early triad system is **38**, which was reported in 1985 [213]. The triad is similar to **35**, but the secondary electron donor is a dimethylaniline species. The bicyclic linkages joining the components preclude large-scale folding of the molecule, and subsequent "short circuiting" as was observed in **37**. The photochemistry of triad **38** is similar to that observed for **35**, and the lifetime of the final state in butyronitrile solution at ambient temperatures is $2.45 \mu\text{s}$.

Compounds related to **38** have been used to study the dependence of electron

**37****38**

transfer rate constants on parameters such as solvent and temperature [60, 116]. A system featuring a zinc porphyrin and a more easily oxidized secondary electron donor (D) carries out photoinduced electron transfer at 5 K, and the resulting spin-polarized $D^{\bullet+}$ - P_{Zn} - $Q^{\bullet-}$ biradical was observed by EPR spectroscopy [66]. Although EPR spectroscopy has been used effectively in the study of radical pair states in photosynthetic reaction centers, relatively few examples exist of similar studies in model compounds [99, 136, 214, 215]. This is partly due to the fact that relatively few synthetic systems yield long-lived charge-separated biradical states at the low temperatures that are ideal for EPR experiments.

Triad **39** was reported by Borovkov and coworkers [82]. Although a model for the porphyrin moiety of these compounds has an excited singlet state lifetime of 17.4 ns in acetone solution, the corresponding lifetimes for triad **39** and dyad **40** are 0.41 and 0.77 ns, respectively. The quenching is attributed to photoinduced electron transfer to form a porphyrin–quinone charge-separated state. From these data and Eq. 6, quenching rate constants of $2.4 \times 10^9 \text{ s}^{-1}$ and $1.2 \times 10^9 \text{ s}^{-1}$ may be calculated for **39** and **40**, respectively. The similarity of structures suggests that the increase in electron transfer quenching of the porphyrin in triad **39** relative to dyad **40** may be attributed to the fact that in **39**, two photoinduced electron transfer pathways operate in parallel to compete with decay of the excited state by other pathways (see below, Section 2.5.2). Of course, the increase in quantum yield of electron transfer is relatively small in **39** because the quenching of the porphyrin singlet state by a single quinone is relatively efficient. However, it is easy to see that if this was

not the case, the quantum yield of the charge-separated state could be increased considerably by the availability of the second pathway.

One of the advantages of quinone-based acceptors is that they are capable not only of participating in electron transfer, but also of carrying on proton transfer processes [216, 217]. For example, triad **41** illustrates a strategy for slowing charge recombination based on coupling photoinduced electron transfer to a proton transfer process [217]. Triad **41** features a quinone internally hydrogen bonded to a carboxylic acid group; no such hydrogen bonding is possible in related model triads. The photochemical properties of these molecules were studied using steady-state and transient absorption and emission spectroscopies in three solvents: benzonitrile, dichloromethane and chloroform. Each of the triads undergoes photoinduced electron transfer from the porphyrin singlet state (C^1P-Q) to yield the charge-separated state $C-P^{+}-Q^{\bullet-}$. In all of these triads electron transfer from C competes with fast electron-hole recombination ($k \sim 10^{12} \text{ s}^{-1}$) to yield a final $C^{+}-P-Q^{\bullet-}$ state. Triad **41** produces the final state with a quantum yield of 0.22 in benzonitrile, which is a factor of ~ 2 higher than for reference triads. It is postulated that following the initial photoinduced electron transfer in **41**, a fast ($k \sim 10^{12} \text{ s}^{-1}$) proton shift from the carboxylic acid to the quinone anion radical competes with the recombination reaction to produce a proton-shifted state ($C-P^{+}-Q^{\bullet-}H \cdots ^-OOC$). Such a fast proton shift is expected due to the marked increase in pK_a at the quinone site (the pK_a of a model protonated naphthoquinone is ~ -6 while the pK_a of the semiquinone is ~ 5). The new proton-shifted state has an increased lifetime, and this augments the yield of electron donation by C. The increased lifetime of the proton-shifted state is attributed to the lower driving force for electron-hole recombination to the high-energy ground state ($C-P-Q^{\bullet+}H \cdots ^-OOC$) in which the quinone is protonated. Assuming a reorganization energy of $\sim 1 \text{ eV}$, the proton transfer step changes the recombination step from a faster rate in the Marcus inverted region ($\sim 1.5 \text{ eV}$ driving force) to a slower rate in the normal region ($\sim 0.5 \text{ eV}$).

The fact that the pK_a of the various oxidation states of quinones differ dramatically has been exploited in a recent design of artificial systems that mimic the light-driven transmembrane proton transport characteristic of natural photosynthesis [218]. Triad artificial reaction centers structurally related to **41** were vectorially inserted into the phospholipid bilayer of a liposome (vesicle) such that the majority of the quinone moieties are near the external surface of the membrane, and the majority of the carotenoids extend inward, toward the interior surface. The membrane

also contains a lipophilic quinone, Q_s , that can readily diffuse in the membrane. Excitation of the porphyrin of the triad generates $C^{*+}-P-Q^{-}$, which donates an electron to Q_s . The resulting semiquinone radical anion is protonated near the exterior surface of the liposome, diffuses through the bilayer, and is oxidized near the interior liposome surface by the carotenoid radical cation. The result is a protonated quinone, Q_sH^+ , which is a strong acid ($pK_a \sim -5$) and releases its proton into the interior volume of the liposome. Thus, the system is a proton pump that uses light energy to build up proton motive force inside the liposome. A transmembrane proton motive force of about 4 kcal mol^{-1} may be established in this way. In later work, an ATP synthase enzyme from spinach chloroplasts has been inserted into the liposomal membrane. The enzyme uses the light-generated proton motive force to synthesize ATP from ADP and inorganic phosphate [219]. Thus, the final step of the bacterial photosynthetic process outlined above has been mimicked using porphyrin-based systems.

2.4.2 Triads with Diporphyrin Components

Interporphyrin photoinduced electron transfer can of course be the basis of light-driven charge separation in more complex systems. For example, triad **42** is similar in structure to dyad **1**, with the addition of a carotenoid moiety, which can serve as a secondary donor as in **35** [13]. Excitation of **42** in dichloromethane with a laser pulse at 590 nm creates two porphyrin first excited singlet states, $C-^1P_{Zn}-P_F$ and $C-P_{Zn}-^1P_F$. As with **1**, both states decay at least in part by photoinduced electron transfer to give an initial $C-P_{Zn}^{*+}-P_F^{-}$ charge-separated state. This state can recombine to the ground state, but as with the other triads discussed above, electron donation from the carotene competes with this to yield a final $C^{*+}-P_{Zn}-P_F^{-}$ state with an overall quantum yield of 0.32 with 590-nm excitation. The lifetime of this final state is 240 ns.

A study by Sessler and coworkers of $P-P_{Zn}-Q$ triads with structures closely related to that of tetrad **53** (see below) has shown remarkably rapid photoinduced electron transfer from the distal free base porphyrin to the quinone. Singlet energy transfer from the free base to the proximal zinc porphyrin on such a time scale is deemed unlikely for thermodynamic reasons, since the first excited singlet state of the zinc

42

moiety is at higher energy than that of the free base. Thus, charge separation is envisioned to occur by long-range electron transfer from the free base porphyrin, where the proximal zinc porphyrin mediates electron transfer via a superexchange mechanism [73, 220].

2.4.3 Triads with Fullerene Components

As described above, photoinduced electron transfer studies in porphyrin–fullerene dyads demonstrated that charge-separated states can be produced in high yield, and that they have long lifetimes relative to quinone-containing dyads. These properties of fullerene systems suggest that they might be ideal components of more complex systems, where slow charge recombination would favor evolution of a charge-separated state into a longer-lived species via multistep electron transfers. This is indeed the case, as illustrated by carotene–porphyrin–fullerene triad **43** [136, 154, 156]. The photochemistry of this triad may be discussed with reference to Figure 6, which shows the relevant high-energy states and decay pathways. Time-resolved spectroscopic studies have shown that at ambient temperatures in 2-methyltetrahydrofuran solution, excitation of the porphyrin moiety yields C^1P-C_{60} , which decays in 10 ps by electron transfer to the fullerene to generate $C^{+}P^{+}-C_{60}^{--}$ (step 3 in Figure 6, $k_3 = 1.0 \times 10^{11} \text{ s}^{-1}$). Also, the fullerene excited singlet state accepts an electron from the porphyrin to yield $C^{+}P^{+}-C_{60}^{--}$ ($k_2 = 3.1 \times 10^{10} \text{ s}^{-1}$). The overall quantum yield of $C^{+}P^{+}-C_{60}^{--}$ by these two pathways is essentially unity. Secondary electron transfer from the carotenoid (step 4) competes with charge recombination by step 7 to give the final $C^{+}-P-C_{60}^{--}$ charge-separated state. The rise time of this state is 80 ps, and the overall yield is ~ 0.14 , as determined by the comparative method. The $C^{+}-P-C_{60}^{--}$ state decays in 170 ns exclusively by charge recombination to produce the carotenoid triplet state ($\Phi_t = 0.13$). Decay of $^3C-P-C_{60}$ occurs in 4.9 μs ($k_{10} = 2.0 \times 10^5 \text{ s}^{-1}$).

Unlike the situation with the quinone- and imide-based acceptors, photoinduced electron transfer is also observed in frozen organic glasses down to at least 8 K. For example, excitation of the porphyrin moiety of **43** in a 2-methyltetrahydrofuran glass at 77 K is followed by appearance of the $C^{+}-P-C_{60}^{--}$ charge-separated state, which is formed with a quantum yield of ~ 0.10 . The rise time for $C^{+}-P-C_{60}^{--}$ is 770 ps, which is presumably the reciprocal of $(k_4 + k_7)$ at this temperature.

The decay of the carotenoid radical cation absorption of $C^{+}-P-C_{60}^{--}$ occurs on the micro second time scale in the frozen glass. It is accompanied by the rise of $^3C-P-C_{60}$ generated by charge recombination of the $C^{+}-P-C_{60}^{--}$ biradical, which is formed with a quantum yield of ~ 0.07 . The major component of the decay of the $^3C-P-C_{60}$ transient has a time constant of 10 μs , which is a typical lifetime for a carotenoid triplet state. The absorption of $C^{+}-P-C_{60}^{--}$ at 77 K does not decay exponentially, but an “average” decay rate of $7.5 \times 10^5 \text{ s}^{-1}$ may be calculated from the data [155]. Time-resolved experiments have allowed detection of the EPR resonances of the $C^{+}-P-C_{60}^{--}$ biradical and $^3C-P-C_{60}$. The spin-polarization of the carotenoid triplet spectrum verifies formation of this state by the radical pair

Figure 6. Transient states and interconversion pathways for carotenoporphyrin–fullerene triad **43**.

mechanism, wherein the initially formed singlet biradical of $C^+-P-C_{60}^{\bullet-}$ interconverts with the corresponding triplet biradical, which recombines to give the carotenoid triplet state [136].

The low-temperature formation of $C^+-P-C_{60}^{\bullet-}$ and its recombination to a triplet state allow some interesting and potentially useful magnetic field effects. In the presence of a small (20 mT) static magnetic field, the lifetime of the $C^+-P-C_{60}^{\bullet-}$ charge-separated state in **43** is increased by 50 % [155]. This is ascribed to the effect of the magnetic field on interconversion of the singlet and triplet biradicals. At zero field, the initially formed singlet biradical state is in equilibrium with the three triplet biradical sublevels, and all four states have comparable populations. Decay to the carotenoid triplet only occurs from the three triplet sublevels. In the presence

of the field, the S and T_0 states are still rapidly interconverting, but the T_+ and T_- states are isolated from the other two due to the electronic Zeeman interaction, and are not significantly populated. Under these conditions, recombination to the triplet occurs only from T_0 , and the lifetime of the charge-separated state increases. This effect can be used as the basis for a magnetically controlled optical or optoelectronic switch (AND gate).

The photochemistry of triad **43** has a number of unusual features. For example, it has been mentioned that two-step photoinduced electron transfer to generate long-lived charge separation occurs even at 8 K in a glass. As discussed above, the vast majority of systems based on other electron acceptors fail to undergo charge separation under these conditions [48, 54, 60]. It is generally thought that this failure is due mainly to the fact that upon freezing, the effective solvent dielectric constant decreases dramatically because the solvent dipoles cannot reorient to stabilize the newly formed ions. As mentioned above, studies of porphyrins linked to quinones and related acceptors have shown that the loss of stabilization in going from liquid butyronitrile to a 2-methyltetrahydrofuran glass at low temperatures is ~ 0.8 eV, and that only dyads with a greater driving force for electron transfer can still function at these temperatures [116]. The free energy change for formation of $C-P^{+\bullet}-C_{60}^{\bullet-}$ from $C-^1P-C_{60}$ is only 0.54 eV, based on cyclic voltammetry in benzonitrile. Thus, the fullerene anion radical in **43** must be substantially less susceptible to destabilization in nonpolar solvents than other organic ions such as quinone anion radicals. This is likely due to the fact that the negative charge is spread over a large, delocalized carbon framework. In quinone radical anions, on the other hand, the charge is concentrated on the oxygen atoms, and thus may be more susceptible to specific solvation effects [156]. The low total reorganization energy of fullerenes can also contribute to the differences in electron transfer rates, as discussed above.

A few other triads and more complex systems consisting of a porphyrin linked to two or more fullerene moieties have been reported [150, 159, 221]. The most complex to date is a tetraarylporphyrin linked to four fullerene moieties through double ester-containing bridges to the porphyrin *meso* aryl groups [151]. This molecule is rendered soluble in organic solvents via 16 twelve-carbon aliphatic chains. The porphyrin fluorescence is strongly quenched by the attached C_{60} moieties.

Both simple porphyrin–fullerene dyads and more complex systems may be very useful in artificial photosynthetic or molecular-scale electronic applications, due especially to the low reorganization energy of fullerenes and their low sensitivity to solvent parameters.

2.4.4 Triads with Aromatic Imide Components

Osuka, Mataga, Maruyama and coworkers have synthesized and studied a large variety of molecules that employ imides as acceptors [14–16, 56, 172–179, 182, 186, 222–226]. Representative molecules are triads **44** [179], **45** [174], **46** [175], and **47** [16]. The general photochemistry of these molecules is similar to that observed for

31 and **32**. For example, excitation of zinc porphyrin–pyromellitimide triad **44** in tetrahydrofuran at 532 nm gives the first excited singlet state of the porphyrin, $\text{Im-}^1\text{P}_{\text{Zn}}\text{-Im}$. Picosecond transient absorption studies show that this state decays into the $\text{Im-P}_{\text{Zn}}^{+\cdot}\text{-Im}^{\cdot-}$ charge-separated state in 60 ps. The charge-separated state recombines to give the ground state with a time constant of 100 ps [227]. The charge-separated state is particularly easy to detect in this molecule because of the sharp absorption band of the pyromellitimide radical anion at 715 nm.

**44****45****46**

47

Zinc chlorins are more easily oxidized than their free base counterparts, and this fact has been used in the design of some chlorin-porphyrin-imide triads that demonstrate multistep electron transfer [16]. For example, triad **47** consists of a zinc chlorin linked to a free base porphyrin that also bears a pyromellitimide acceptor moiety. Phenyl linkers join all active constituents. Excitation of the zinc chlorin moiety of **47** in tetrahydrofuran gives $^1\text{CZ-P-Im}$, which decays with a 20-ps time constant to yield $\text{CZ}^{++}\text{-P}^{--}\text{-Im}$. This initial charge-separated state evolves into $\text{CZ}^{++}\text{-P-Im}^{--}$ with a lifetime of 120 ps. The $\text{CZ}^{++}\text{-P-Im}^{--}$ state is formed with an overall quantum yield of 0.90 and decays biphasically with time constants of 110 ns and 400 ns.

Osuka, Maruyama and Mataga have also reported the energy- and electron-transfer properties of a series of carotene-porphyrin-imide triads, such as **48** [172, 173, 178, 228]. They report that excitation of the carotenoid moiety of **48** in tetrahydrofuran solution leads to the formation of a $\text{C}^{++}\text{-P-Im}^{--}$ charge-separated state within 40–50 ps. The state has a lifetime of 15 ns. The $\text{C}^{++}\text{-P-Im}^{--}$ state is also formed upon excitation of the porphyrin, presumably via a route similar to that shown in Figure 5, but with a much slower time constant. The authors suggested that with carotenoid excitation, the $\text{C}^{++}\text{-P-Im}^{--}$ species is formed via direct, long-range electron transfer from the carotene to the imide, involving superexchange coupling through the porphyrin. No porphyrin anionic intermediate was implicated in the process.

C-P-Im triad **49** was prepared in order to further investigate this phenomenon [184]. An electron acceptor moiety based on the 4,5-dinitro-1,8-naphthalenedicarboximide system was used in this triad, as this imide is more easily reduced than pyromellitimide (-0.88 V versus ferrocene/ferrocenium as an internal reference, compared to -1.24 V for the imide moiety of **48**), and can therefore serve as an acceptor for a wider variety of donors. Excitation of the porphyrin moiety of **49**

48

with visible light in benzonitrile solution leads to rapid ($k = 1.0 \times 10^{10} \text{ s}^{-1}$) photo-induced electron transfer to generate in 96 % yield a charge-separated state consisting of the porphyrin radical cation and imide radical anion. As with other triads, the intermediate $\text{C-P}^{+\bullet}\text{-Im}^{\bullet-}$ state decays by two routes: charge recombination to the ground state (analogous to step 3 in Figure 5) and electron transfer from the carotenoid to give the final $\text{C}^{+\bullet}\text{-P-Im}^{\bullet-}$ species (step 4). This final state is formed with a quantum yield of 0.33 and has a lifetime of 430 ns. In contrast to the results reported for **48** and related triads, triad **49** shows no evidence for photoinduced electron transfer from the carotenoid first excited singlet state. For example, with excitation at 556 nm, where the carotenoid moiety absorbs 43 % of the light, the carotenoid radical cation absorption was found to rise with the time constant of the decay of $\text{C-}^1\text{P-Im}$ (99 ps), and no rise time corresponding to the 7.7-ps lifetime of $^1\text{C-P-Im}$ was observed. A variety of other evidence bolstered this conclusion. The reasons for the difference in behavior of these two triads is not clear, although it is possible that a combination of structural differences between the two systems might conspire to favor transfer from the carotenoid in **48** [184].

2.4.5 Triad with a Viologen Component

An interesting and much more complex system is **50**, which consists of a rigid array containing a porphyrin donor and two electron acceptors; a quinone and a methyl

viologen derivative [188]. This molecule has a U-shaped conformation in which the bridge curves back toward the porphyrin, bringing the viologen unit to about 10 Å from the center of the porphyrin. Excitation of the porphyrin yields the porphyrin–viologen charge-separated state with a time constant of 330 ps. Charge recombination is biphasic, with lifetimes of 500 ns (~70 %) and tens of μ s (~30 %). There are three possible mechanisms for charge separation. Direct electron donation from the porphyrin to the viologen may occur. Alternatively, an electron may be donated from the porphyrin through the bridge to the naphthoquinone, which may then transfer an electron to the viologen. In principle, electron transfer through the bridge to the viologen, without intermediate reduction of the naphthoquinone could occur as well. However, the experimental data so far do not allow assignment of the mechanism.

2.5 Intramolecular Photoinduced Electron Transfer in Complex Porphyrin-Based Systems: Tetrads, Pentads, and Hexads

The early triad biomimetic systems proved beyond argument the value of the multistep electron transfer strategy for temporal stabilization of photochemically generated charge-separated states. They have been followed by a large number of other triad and more complex systems that demonstrate new principles and approaches to electron transfer that may only be realized in systems including multiple donors and acceptors. Some of these will be illustrated below.

2.5.1 Sequential Multistep Electron Transfer Process: Tetrads

We have reported the preparation and photochemistry of C-P-Q_A-Q_B tetrad **51** [229, 230]. Excitation of the porphyrin moiety of this molecule in dichloromethane solution yields C-¹P-Q_A-Q_B, which decays by electron transfer to the attached naphthoquinone ($k = 6.6 \times 10^{10} \text{ s}^{-1}$) to yield C-P^{•+}-Q_A^{•-}-Q_B. Subsequent electron transfers from carotene to porphyrin and Q_A to Q_B compete with charge recombination to the ground state, and form a sequence of transfers that move the positive

charge to the carotenoid and the negative charge to the benzoquinone to yield a final $C^{*+}\text{-P-Q}_A\text{-Q}_B^{\cdot-}$ charge-separated state. The initial $C\text{-P}^{*+}\text{-Q}_A^{\cdot-}\text{-Q}_B$ species is formed with a quantum yield of 1.0, whereas the $C^{*+}\text{-P-Q}_A\text{-Q}_B^{\cdot-}$ final state is produced with a quantum yield of 0.23 at 298 K and has a lifetime of 460 ns.

A closely related tetrad featuring two porphyrin moieties and a single naphthoquinone acceptor has also been reported [13]. Excitation of either porphyrin moiety of C-P-P-Q in anisole solution is followed by rapid ($>10^8\text{ s}^{-1}$) singlet-singlet energy transfer between the two porphyrins, whose absorption and emission spectra are essentially identical. C-P- 1 P-Q decays by photoinduced electron transfer to the quinone with a rate constant of $2.4 \times 10^8\text{ s}^{-1}$. Sequential transfer of the radical cation "hole" to the second porphyrin, and then to the carotenoid yields a final $C^{*+}\text{-P-P-Q}^{\cdot-}$ state with a quantum yield of 0.25 and a lifetime of 2.9 μs .

Based on the results for **51**, a second C-P- $\text{Q}_A\text{-Q}_B$ molecular tetrad **52** was prepared in an attempt to increase the quantum yield of long-lived charge separation [231]. This tetrad was engineered so that the electronic coupling between the porphyrin and adjacent naphthoquinone moiety is reduced, relative to **51**, by insertion of a methylene group in the linkage. Time-resolved fluorescence studies showed that excitation of the porphyrin moiety of **52** in dichloromethane solution is followed by photoinduced electron transfer to yield an initial $C\text{-P}^{*+}\text{-Q}_A^{\cdot-}\text{-Q}_B$ state, which is formed with a rate constant of $2.3 \times 10^9\text{ s}^{-1}$ and a quantum yield of 0.87. In chloroform, the rate is $4.1 \times 10^9\text{ s}^{-1}$ and the quantum yield is 0.94. Transient absorption studies revealed that this state evolves by subsequent electron transfer pathways similar to those for **51** to a final $C^{*+}\text{-P-Q}_A\text{-Q}_B^{\cdot-}$ charge-separated state whose lifetime is 7.4 μs in dichloromethane and 740 ns in chloroform. The quantum yield of the final state is 0.49 in dichloromethane and 0.57 in chloroform. The yield of the final state is substantially higher than that in tetrad **51** in spite of the fact that the quantum yield of the initial $C\text{-P}^{*+}\text{-Q}_A^{\cdot-}\text{-Q}_B$ species is lower. This is because the weaker electronic coupling interaction between the porphyrin and Q_A in **52** slows down charge recombination of $C\text{-P}^{*+}\text{-Q}_A^{\cdot-}\text{-Q}_B$, but has little effect on the rate constants of the electron transfer pathways that allow evolution of $C\text{-P}^{*+}\text{-Q}_A^{\cdot-}\text{-Q}_B$ into the final $C^{*+}\text{-P-Q}_A\text{-Q}_B^{\cdot-}$ state, since these do not involve the porphyrin-quinone interaction. This reduction in electronic coupling also decreases both the rate of the initial photoinduced electron transfer reaction and the charge recombination of the final $C^{*+}\text{-P-Q}_A\text{-Q}_B^{\cdot-}$ state, relative to **51**.

**53**

A variety of other porphyrin–quinone-based multicomponent systems bearing four or more donor and acceptor moieties have been reported. For example, P-P-P-Q tetrad **53** and related compounds have been reported by Sessler and coworkers [64, 65, 73, 220, 232–236]. Fluorescence and time-resolved absorption experiments with **53** were interpreted in terms of rapid (~ 10 -ps) singlet–singlet energy transfer between the porphyrin units in the linear array and extremely fast (< 350 -fs) photo-induced electron transfer to the quinone from the proximal porphyrin excited singlet state to give a charge-separated species.

Osuka, Maruyama, Mataga and coworkers have reported a variety of closely related supramolecular systems such as **54**, in which a stacked, cofacial zinc dipor-

**54**

phyrin unit is linked to a monomeric zinc porphyrin, which in turn bears a benzoquinone moiety ($P_{Zn2}-P_{Zn}-Q$) [11, 72, 237]. Excitation of the monomeric porphyrin moiety of **54** yields $P_{Zn2}-^1P_{Zn}-Q$, which decays by photoinduced electron transfer to give $P_{Zn2}-P_{Zn}^{++}-Q^{--}$. Detection of a long-lived (nanosecond) charge-separated state suggests that electron transfer from the diporphyrin unit to the monomeric porphyrin radical cation competes with charge recombination to yield $P_{Zn2}^{++}-P_{Zn}-Q^{--}$. Excitation of the diporphyrin unit also yields a charge-separated state; via either singlet-singlet energy transfer to the monomeric porphyrin followed by electron transfer as described above, or direct electron transfer to the quinone moiety.

In $P_{Zn2}-P_{Zn}-Im$ tetrad **55**, the photochemistry in tetrahydrofuran is more complex [179]. The porphyrins in the P_{Zn2} unit are stacked, and interact so as to lower the energy of the first excited singlet state by 0.16 eV and the oxidation potential by 0.24 V, relative to a monomeric porphyrin model. Thus, the P_{Zn2} unit is both an excitation and a hole sink, relative to P_{Zn} . Excitation of P_{Zn} yields $P_{Zn2}-^1P_{Zn}-Im$, which decays with a time constant of 35 ps by two competing pathways. One of these is energy transfer to the stacked porphyrins, yielding $^1P_{Zn2}-P_{Zn}-Im$, which does not undergo photoinduced electron transfer, and decays to the ground state. The second is electron transfer to the pyromellitimide, giving $P_{Zn2}-P_{Zn}^{++}-Im^{--}$. Competing with the decay of this species by charge recombination is electron transfer from P_{Zn2} ($k = 4.3 \times 10^9 \text{ s}^{-1}$) to give $P_{Zn2}^{++}-P_{Zn}-Im^{--}$. This final state has a lifetime of 2.5 μs . The quantum yield of the final state would depend upon the excitation wavelength, but is limited by two factors: the competition for the excited state of P_{Zn} by both energy transfer to P_{Zn2} and electron transfer to Im , and the relatively slow electron transfer from P_{Zn2} to P_{Zn}^{++} , which leads to a considerable loss of the intermediate $P_{Zn2}-P_{Zn}^{++}-Im^{--}$ species to charge recombination.

Supramolecular species with imide acceptors have been designed as sophisticated optical switches [183, 238, 239], tetrad **56** being one example [238]. These function via sequential two-photon absorptions that result in photoinduced electron transfer

phenomena leading to new charge-separated species, or changes in rate constants for electron transfer processes.

2.5.2 Sequential and Parallel Multistep Electron Transfer Process: Pentads

In pentad **57** and related pentads, the sequential electron transfer is extended to five donor–acceptor moieties [240–242]. This molecule also conveniently illustrates a second electron transfer strategy that is useful in multicomponent systems—parallel multistep electron transfer.

Spectroscopic studies of this molecule reveal the photochemistry illustrated in Figure 7, which shows the relevant transient species and their possible inter-conversion routes. The pentad is designed so that photoinduced electron transfer from the free base porphyrin to the attached naphthoquinone can be followed by a cascade of electron transfer pathways which converge upon a final $C^{+}\text{-P}_{\text{Zn}}\text{-P-Q-Q}^{-}$ charge-separated state. The process begins with excitation of the free base porphyrin moiety. This can occur via direct absorption of light, or by singlet–singlet energy transfer from the attached zinc porphyrin. The rate constant for the energy transfer process (step 1 in Figure 7) is $2.3 \times 10^{10} \text{ s}^{-1}$ in chloroform solution, as determined from global analysis of the time-resolved fluorescence of the molecule at 14 wavelengths. The energy transfer quantum yield is about 90 %.

Figure 7. Transient states and interconversion pathways for carotenodiporphyrin-diquinone pentad **57**.

The free base porphyrin first excited singlet state decays in part by electron transfer to the attached naphthoquinone (step 2 in Figure 7) to produce $\text{C-P}_{\text{Zn}}\text{-P}^+\text{-Q}^{\bullet-}\text{-Q}$. The rate constant is $7.1 \times 10^8 \text{ s}^{-1}$, and the quantum yield is 0.85. This initial charge-separated state can in principle decay to the ground state through charge recombination (step 10). However, two electron transfer steps operating in parallel compete with recombination. One of these, step 3, involves electron migration from the naphthoquinone radical anion to the attached benzoquinone, which is a better electron acceptor. The other, step 4, is electron donation from the zinc porphyrin to the free base porphyrin radical cation. This reaction has a reasonable driving force, as the zinc stabilizes the positive charge on the macrocycle. Although the two new intermediates can decay by charge recombination, these reactions are expected to be slow compared to step 10 because the charges are farther apart (less electronic coupling). The two intermediates can in turn undergo electron transfer by steps 5, 6, and 7 to yield yet another two intermediates that both decay to $\text{C}^+\text{-P}_{\text{Zn}}\text{-P-Q-Q}^{\bullet-}$. This ultimate state may be readily detected spectroscopically by observation of the carotenoid radical cation absorption in the 950-nm region. In chloroform at ambient temperatures, 650-nm excitation yields the final state with an overall quantum yield of 0.83. As this yield is essentially the same as that of the initially formed $\text{C-P}_{\text{Zn}}\text{-P}^+\text{-Q}^{\bullet-}\text{-Q}$ species, the parallel electron transfer pathways compete very efficiently with step 10. The lifetime of $\text{C}^+\text{-P}_{\text{Zn}}\text{-P-Q-Q}^{\bullet-}$ is 55 μs in chloroform solu-

tion. In dichloromethane solution, the lifetime of $C^{*+}\text{-P}_{Zn}\text{-P-Q-Q}^{\bullet-}$ is increased to about 200 μs , and the quantum yield drops to 0.6.

The use of sequential and parallel multistep electron transfer pathways in the pentad has increased the lifetime of charge separation from picoseconds in porphyrin–quinone dyads to hundreds of microseconds, a factor of 10^8 . By successful molecular engineering, this has been achieved while maintaining a quantum yield near unity and preserving a significant fraction of the photon energy as chemical potential in the final charge-separated state. Such molecules show that biomimetic systems can perform essentially as well as natural photosynthesis in these respects.

Achieving a high quantum yield in pentad **57** may be ascribed in large part to the use of parallel electron transfer to compete with charge recombination steps. The use of this strategy is also illustrated by tetrads **51** and **52** (see above).

Another example of the parallel multistep strategy is given by pentad **58**, which features a porphyrin–quinone system bearing three carotenoid secondary donors [243]. Excitation of the porphyrin moiety of model C-P-Q triad **59** leads to the formation of a charge-separated state $C^{*+}\text{-P-Q}^{\bullet-}$ with an overall quantum yield of 0.044 in benzonitrile solution. Electron transfer from the porphyrin first excited singlet state gives $C\text{-P}^{*+}\text{-Q}^{\bullet-}$ with a quantum yield of ~ 1.0 . However, electron transfer from the carotenoid to the porphyrin radical cation to form the final state does not compete well with charge recombination of $C\text{-P}^{*+}\text{-Q}^{\bullet-}$, reducing the yield. Pentad **58**, $C_3\text{-P-Q}$, features carotenoid, porphyrin and quinone moieties closely related to those in the triad. Excitation of this molecule gives a $C^{*+}\text{-P}(C_2)\text{-Q}^{\bullet-}$ state with higher quantum yield than in the triad (0.073). The enhanced yield is ascribed to the fact that three carotenoid-to-porphyrin electron donation pathways operating in parallel compete with charge recombination of $C_3\text{-P}^{*+}\text{-Q}^{\bullet-}$. The yield does not increase by the statistically predicted factor of three because there is a small difference in the stability of the porphyrin radical cation in the triad **59** and the pentad **58**. This difference slightly increases the rate of charge recombination of $C_3\text{-P}^{*+}\text{-Q}^{\bullet-}$ while slightly decreasing the rate of forward electron transfer leading to the final $C^{*+}\text{-P}(C_2)\text{-Q}^{\bullet-}$ species.

2.5.3 An Artificial Photosynthetic Antenna–Reaction Center System

Photosynthetic antenna function is based on singlet–singlet energy transfer among chromophores. This process has been mimicked in artificial, covalently linked arrays. For example, metalated and free base porphyrins have been linked with alkyne units to form dimers, trimers, tetramers, pentamers and more complex supermolecules that absorb light and rapidly and efficiently transfer singlet excitation to energy sinks such as a free base porphyrin moiety [244–250]. Some molecules of these types have been designed to act as photonic “wires” [251] and gates [252]. Other porphyrin arrays with demonstrated or potential antenna function have been reported [253].

Given the progress made in the mimicry of both photosynthetic antennas and

reaction centers, a next step would be to link an artificial light-harvesting array with a synthetic reaction center to produce a functional energy conversion assembly. Indeed, a model photosynthetic antenna consisting of four covalently linked zinc tetraarylporphyrins, $(P_{ZP})_3-P_{ZC}$, covalently joined to a free base porphyrin-fullerene artificial photosynthetic reaction center, $P-C_{60}$, to form $(P_{ZP})_3-P_{ZC}-P-C_{60}$, hexad **60**, has been recently reported [254].

In order to evaluate the performance of hexad **60**, rate constants were extracted from the steady-state and time-resolved spectroscopic data. The time-resolved fluorescence and absorption data yield a time constant of 700 ps that is associated with the zinc porphyrin moieties. The shortening of the zinc porphyrin singlet lifetime from 2.4 ns in tetrad $(P_{ZP})_3-P_{ZC}$ to give a 700-ps component in a model pentad, $(P_{ZP})_3-P_{ZC}-P$, and **60** is a result of singlet-singlet energy transfer from the zinc porphyrins to the free base porphyrin. In **60**, fluorescence from the free base porphyrin is quenched from its usual lifetime of ~ 10 ns to such a degree that fluorescence is no longer observable. The picosecond transient absorbance results yield additional time constants of 3 ps, 12 ps, and 1330 ps.

The model chosen for interpretation of the kinetic and spectroscopic data dealing with singlet energy and electron transfer in hexad **60** is shown in Figure 8. The energies of the various spectroscopic states were determined from the wavenumber average of the longest-wavelength absorption and shortest-wavelength emission maxima of **60** and appropriate model compounds. The zinc porphyrin first excited

Figure 8. Transient states and interconversion pathways for antenna–reaction center complex–hexad 60.

singlet states lie at 2.06 eV, whereas the energy of $(P_{ZP})_3-P_{ZC}-^1P-C_{60}$ is 1.96 eV above the ground state. The fullerene excited singlet state is not shown in the diagram, as the results show that this state was not significantly populated by either direct excitation or energy transfer in these experiments. The energy of the $(P_{ZP})_3-P_{ZC}-P^{*+}-C_{60}^{*-}$ charge-separated state was estimated as 1.43 eV, based on the electrochemically determined oxidation potential of a model porphyrin (0.84 V versus SCE) [61] and reduction potential of a model fullerene (−0.59 V versus SCE) [255].

The rate constant for photoinduced electron transfer k_4 and the charge recombination rate constant k_5 are directly observed experimentally. The reciprocal of the 3-ps time constant detected in the transient absorption experiments, equals k_4 , $3 \times 10^{11} \text{ s}^{-1}$. This assignment is verified by the results for a model P- C_{60} dyad, where the same value was obtained for the rate constant for photoinduced electron transfer. The charge recombination of $(P_{ZP})_3-P_{ZC}-P^{*+}-C_{60}^{*-}$ is associated with the 1330-ps decay component observed in transient absorption, as demonstrated by the spectral signature of the fullerene radical anion with absorption in the 1000-nm region. This lifetime is within a factor of 2.5 of the lifetime observed for the $P^{*+}-C_{60}^{*-}$ in a model dyad (480 ps).

The values for the singlet energy transfer rate constants k_1 and k_3 do not appear directly in the experimental decays. Solution of a set of rate differential equations using the experimentally measured lifetimes of 12 ps and 700 ps as constants yields values of $2.0 \times 10^{10} \text{ s}^{-1}$ for k_1 and $4.1 \times 10^9 \text{ s}^{-1}$ for k_3 . The value thus obtained for k_1 is in excellent agreement with the results of Hsiao and coworkers [245], who

measured a rate constant of $1.9 \times 10^{10} \text{ s}^{-1}$ for singlet energy transfer between two zinc porphyrins in a linear trimeric array of zinc porphyrins with diphenylethyne linkages very similar to those in **60**.

The singlet–singlet energy transfer between the central zinc porphyrin in the antenna of **60** and the free base porphyrin (k_3) is slow (240 ps) compared with that among the zinc porphyrins (k_1) (50 ps). Thus, the rate constant k_3 is a bottleneck that limits the quantum yield of the final charge-separated state $(\text{P}_{\text{ZP}})_3\text{-P}_{\text{ZC}}\text{-P}^{++}\text{-C}_{60}^{*-}$. Structural modifications are envisioned to improve the performance of this antenna–reaction center device.

The quantum yield of $(\text{P}_{\text{ZP}})_3\text{-P}_{\text{ZC}}\text{-P}^{++}\text{-C}_{60}^{*-}$ is wavelength-dependent. Based on light absorbed by the free base porphyrin the yield is unity, due to the very large rate constant for photoinduced electron transfer, k_4 . The quantum yield based on excitation of the zinc porphyrins in the antennas is 0.70. In this process, the light-gathering power of the system is increased tremendously at many wavelengths, as four zinc porphyrin moieties feed excitation energy to the reaction center.

2.6 Conclusions

Even though a considerable number of electron donor–acceptor systems involving porphyrins have been illustrated or outlined above, this review only serves as a preface to this dynamic field of research. All of the multicomponent constructs presented herein depend upon strong covalent bonds to maintain structural integrity and control the degree of interchromophore interactions. The covalent approach is an excellent way to precisely tune and control electronic coupling and other interactions. The examples given demonstrate that porphyrins are remarkable building blocks for the molecular engineer. They feature strong absorption in the visible region of the spectrum and tunable redox properties. A well-developed synthetic chemistry provides ready access to modifications of the porphyrin periphery, central metal, metal ligands and π -electron system in order to tune their redox and photophysical properties. Moreover, related chemistry can be used for the covalent attachment of the required electron or energy donors and acceptors. These properties suggest that porphyrin donor–acceptor systems will continue to be useful as simple systems in which to study the basic principles of energy and photoinduced electron transfer, and as model systems for understanding biological energy and electron transfer processes such as photosynthesis. Also, it is likely that porphyrin-based systems will be important in more applied efforts such as the design of molecular-scale photonic or optoelectronic devices, solar energy-harvesting systems, sensors, and as components of membrane-linked constructs that mimic the complex processes of biological systems.

3 Covalently Linked Systems Containing Metal Complexes

Franco Scandola, Claudio Chiorboli, Maria Teresa Indelli, and Maria Anita Rampi

3.1 Introduction

3.1.1 Scope and Limitations

Electron transfer (ET) is the single most important chemical reaction. Indeed, it is: (i) an elementary process amenable to very detailed theoretical description and experimental investigation; (ii) the key step of a number of biological processes of enormous relevance to life; and (iii) a fundamental feature of many processes of great technological impact. This handbook emphasizes the central role of ET in chemistry, its volumes, sections, and chapters reflecting the wide spectrum of ET aspects currently being of interest from both fundamental and practical viewpoints. The aim of this chapter is to provide an overview of ET in covalently linked systems containing metal complexes.

The minimal set for any ET process includes two redox active molecular units, an electron donor A, and an electron acceptor B. When A and B are free species in solution, the ET process is bimolecular.

Bimolecular ET processes are far from ideal from a mechanistic standpoint, as the experimental kinetics is complicated by diffusion effects and the spatial relationship between A and B is completely undefined. If, on the other hand, A and B are pre-assembled in a *supramolecular* structure, the ET process becomes unimolecular, the kinetics is expected to be free from diffusional artifacts, and the spatial relationship between A and B may be to some extent defined. Although *supramolecular* systems based on “weak” interactions are interesting as well (see Volume III, Part 2, Chapters 4–8), the present review is specifically concerned with systems where the A and B units are *covalently linked* via a suitable bridging group, L.

A fundamental aspect of unimolecular ET processes must be pointed out. In difference to bimolecular reactions—where exergonic ET processes can be simply triggered by mixing the reactants—for a supramolecular species in its ground state any intercomponent ET process is, by definition, energetically uphill. Thus, inter-component ET in a supramolecular system must always be induced “externally”. The most obvious, though not unique, way to induce unimolecular ET is to excite electronically one of the molecular components. The sudden increase in oxidizing and reducing power of the unit that undergoes photoexcitation can make inter-component ET thermodynamically allowed. Two possible schemes for photo-induced electron transfer (PET) are shown in Figure 1, these differing in whether

Photoinduced Electron Transfer (PET)

Photoinduced Charge Shift (PCS)

Figure 1. Different types of photoinduced electron transfer processes (PET) within a covalently linked system: (a) reductive PET; (b) oxidative PET; (c) charge shift.

the photoexcited molecular component plays the role of donor (oxidative PET, Figure 1b) or acceptor (reductive PET, Figure 1a). For obvious reasons, in the absence of chemical complications (i.e., if A^+-L-B^- or A^--L-B^+ are not intrinsically labile or are not scavenged by external species), a PET system is always reversible, that is, the primary products of the forward ET process spontaneously undergo back ET to regenerate the starting ground-state system. In the literature, the photoinduced forward process and the back reaction are often called “charge separation” and “charge recombination”. This notation is strictly appropriate only for neutral systems (e.g., organic donor–acceptor systems), but can be used in a conventional sense also for charged species (as for inorganic donor–acceptor systems). An additional, though more complex, scheme for triggering intramolecular electron transfer with light is photoinduced charge shift (PCS). In this case, oxidative or reductive bimolecular electron transfer quenching is used to generate a thermodynamically unstable redox isomer of the covalently linked system, that relaxes by intramolecular electron transfer to the thermodynamically favored species (before undergoing the final bimolecular recombination step). The process is depicted in Figure 1c for the case of oxidative bimolecular quenching.

A large number of covalently linked systems are currently being synthesized and investigated, differing in the nature of A, B, and L, as well as in the number of functional units in the supramolecular system (nuclearity). It is common to call simple two-component donor–acceptor systems such as that of Eq. 2 “dyads”, and progressively more complex systems “triads”, “tetrads”, “pentads”, etc.. Systems where all the A and B units are organic molecules are dealt with in Chapter 1 of this section. The present chapter deals with systems where at least one of the A/B functional units is a transition metal coordination compound. From this definition, however, are excluded: (a) systems where A and/or B are porphyrins or related species (dealt with in Chapter 2); and (b) systems of high nuclearity with dendritic structures (dealt with in Chapter 9).

As outlined below (Section 3.1.3), electronic energy transfer (EnT) between a donor and an acceptor (Figure 2) is a process that shares with electron transfer a number of formal and substantial similarities. In bimetallic dyads, energy transfer and PET are often strongly intertwined, either as competitive or as mechanistically related processes. Therefore, the discussion will not be strictly limited to ET processes, but will include, when required, EnT results as well.

Electronic Energy Transfer (EnT)

Figure 2. Electronic energy transfer within a covalently linked system.

Figure 3. An example of a covalently linked supramolecular species, dissected into its molecular components.

3.1.2 Covalently Linked Systems as Supramolecular Species

As represented in Figures 1 and 2, a covalently linked system undergoing PET (or EnT) is a supramolecular species containing three types of subunits: an electron (energy) donor; an electron (energy) acceptor; and a bridge. In this schematic picture, the donor and the acceptor are “active” components directly involved in the transfer process, whereas the bridge is assumed to have a predominantly structural role (see, however, the discussion in Section 3.1.3). For real supramolecular systems, the identification of molecular components may not always be as straightforward as indicated in Figure 1.

For classical supramolecular systems [1–3], made of individually existing molecular species assembled together by weak interactions (electrostatic, hydrogen bonding, or host–guest), the dissection into molecular components is obvious. The situation becomes more complicated when the definition of supramolecular systems is broadened to include covalently linked systems [4, 5]. Consider, for example, the binuclear complex in Figure 3. On the basis of simple bonding arguments, this species could be considered as a large, single molecule. It can usefully be viewed as a supramolecular species, however, to the extent to which some of its fragments (molecular components) possess intrinsic (i.e., context-independent, or at best slightly perturbed) properties. Properties relevant to PET are the redox properties and, for the components that undergo excitation, the chromophoric properties. From this standpoint, the system in Figure 3 includes two easily identifiable molecular components, the ruthenium polypyridine donor and the rhodium polypyridine acceptor, whose intrinsic chromophoric and redox properties closely resemble those of $\text{Ru}(\text{Me}_2\text{phen})_2(\text{bpy})^{2+}$ and the $\text{Rh}(\text{Me}_2\text{bpy})_2(\text{bpy})^{3+}$ model compounds. These two active components are separated by a biphenylene fragment, which can be considered as a bridge. This distinction is justified if one looks at PET in terms of the frontier orbitals of the various fragments (Figure 4) where the bridge is characterized by HOMO and LUMO levels lying far away in energy from those of the active components. This is true for the system of Figure 3, where conjugation is prevented by ring-to-ring twisting (not shown in this schematic picture), both within

Figure 4. A schematic representation of photoinduced electron transfer in terms of frontier orbitals of donor (A), acceptor (B), and bridge (L) fragments.

the biphenylene bridge and between the bridge and the bipyridine fragments. This condition is met by most of the bridges dealt with in this review. Some exceptions will be discussed later.

3.1.3 Intercomponent Processes: A Short Summary

In covalently linked systems, the most important intercomponent processes are PET and EnT (Figures 1 and 2). The theoretical aspects of such processes are dealt with in detail in Volume I, Part 1, Chapter 1. For the sake of convenience, this section summarizes some the basic concepts that will be used in the following discussion.

Electron transfer

For a supramolecular system, A-L-B, the driving force of an excited-state electron transfer process can be easily calculated (Eq. 3) on the basis of electrochemical and spectroscopic data on the isolated molecular components (with, in case, small corrections for electrostatic work terms) [6]. For the case of oxidative PET (Figure 1b; Eq. 2), the relevant expression is given in Eq. 3.

$$\begin{aligned} \Delta G(^*A-L-B/A^+-L-B^-) &= E^0(A^+/A) - E^0(B/B^-) \\ &\quad + E_{coul}(A-L-B) - E_{coul}(A^+-L-B^-) \\ &\approx -E(A)^{0-0} + E^0(A^+/A) - E^0(B/B^-) \\ &\quad + E_{coul}(A-L-B) - E_{coul}(A^+-L-B^-) \end{aligned} \quad (3)$$

In Eq. 3, $\Delta G(^*A-L-B/A^+-L-B^-)$ is the free energy change, $E(A)^{0-0}$ is the excitation energy, $E^0(A^+/A)$ and $E^0(B/B^-)$ are the oxidation and reduction potentials of the molecular components (expressed as one-electron energies, in eV), and $E_{coul}(A-L-B)$ and $E_{coul}(A^+-L-B^-)$ are the Coulombic stabilization energies of reactants and products.

As far as kinetics is concerned, electron transfer processes can be described in terms of quantum mechanical [7–9] or classical [10–14] models. From a quantum mechanical viewpoint, both photoinduced electron transfer (Eq. 2) and charge recombination (Eq. 4) can be viewed as examples of radiationless transitions between

different, weakly interacting electronic states of the supermolecule A-L-B. The probability of such processes is given by a “golden rule” expression of the type [10–13]

$$k_{el} = \frac{4\pi}{\hbar} H_{if}^{el2} FCWD^{el} \quad (5)$$

where H_{if}^{el} is the electronic coupling between the two states interconverted by the electron transfer process and $FCWD^{el}$ is a thermally averaged vibrational Franck–Condon factor (“Franck–Condon-weighted density of states”).

The electronic factor

For a donor–acceptor pair in the absence of any intervening medium (through-space mechanism), the exponential fall-off of the orbital tails leads to an expected exponential decrease of H_{if}^{el} with distance (Eq. 6)

$$H_{if}^{el} = H_{if}^{el}(0) \exp \left[-\frac{\beta}{2} (r_{AB} - r_0) \right] \quad (6)$$

where r_{AB} is the donor–acceptor distance, $H_{if}^{el}(0)$ is the interaction at “contact” distance r_0 , and β is an appropriate attenuation parameter (the $\frac{1}{2}$ factor arises as β was originally defined as the exponential attenuation parameter for rate constant rather than for electronic coupling). For donor–acceptor sites in vacuum, estimated values of β are in the range $2\text{--}5 \text{ \AA}^{-1}$ [14]. Thus, at the donor–acceptor distances usually found in dyads, through-space coupling is expected to be negligible. In dyads, however, the bridging group does not act simply as a passive spacer, but rather as an active connector mediating the donor–acceptor electronic coupling (through-bond mechanism) [14, 15]. A convenient way to account for through-bond electronic coupling is in terms of “superexchange” [14, 16–21]. The essential point is that, although direct interaction between the initial and final states of the electron transfer process is negligible, indirect coupling takes place by mixing with high-energy states of charge transfer character involving the bridge (often called “virtual states”). Two superexchange coupling pathways can be generally envisioned, electron-transfer or hole-transfer involving donor-to-bridge or bridge-to-acceptor charge transfer virtual states (Figure 5). The second-order perturbation expression describing the superexchange coupling is

$$H_{if}^{el} = \frac{H_{ie}H_{fe}}{\Delta E_e} + \frac{H_{ih}H_{fh}}{\Delta E_h} \quad (7)$$

Figure 5. State diagram illustrating superexchange interaction between a donor (A) and an acceptor (B) through a simple bridging group (L). Ψ_h and Ψ_e are the hole- and electron-transfer “virtual” states. For the others symbols, see text.

where H_{ie} , H_{fe} , H_{ih} , H_{fh} , are the appropriate donor–bridge and bridge–acceptor coupling elements (Figure 5) and ΔE_e and ΔE_h are the energy differences between the virtual states and the initial or final state (these energy differences are taken at the transition-state nuclear geometry, where the initial and final state have the same energy). In this expression, the key parameters determining the electron-mediating properties of a bridge are the energy denominators: (i) easily reducible bridges, i.e., bridges with relatively low-energy LUMOs, are good electron-transfer superexchange mediators; (ii) easily oxidizable bridges, i.e., bridges with relatively high-energy HOMOs, are good hole-transfer superexchange mediators.

The above picture involving a single virtual state (of electron- or hole-transfer type) is strictly appropriate for few very simple bridges (e.g., ambidentate ligands such as cyanide, pyrazine) [18, 20]. In dyads, however, bridges have often a modular structure, being made of a sequence of individual weakly interacting units (see, e.g., the dyad of Figure 3). In such a case, not only the chemical nature, but also the length of the bridge will be relevant to its “conducting” properties. This can be seen by extending the superexchange model to involve virtual charge transfer states localized on each single modular unit, as shown schematically in Figure 6, where a three-module bridge is considered and, for the sake of simplicity, only the electron-transfer pathway is shown. In such a case, the appropriate perturbation expression is

$$H_{if}^{el} = \frac{H_{i1}}{\Delta E_{i1}} \frac{H_{12}}{\Delta E_{i2}} \frac{H_{23}}{\Delta E_{i3}} H_{3f} \quad (8)$$

For a bridge involving n identical modular units, the donor–acceptor superexchange coupling is summarized by Eq. 9 (for each pathway).

$$H_{if}^{el} = \frac{H_{i1}H_{nf}}{\Delta E} \left(\frac{H_{12}}{\Delta E} \right)^{n-1} \quad (9)$$

It is seen that for through-bond superexchange interaction, an exponential dependence on number of modular units in the bridge is obtained. For linear bridges,

Figure 6. State diagram illustrating superexchange interaction between a donor (A) and an acceptor (B) through a modular bridge. Ψ_{e1} , Ψ_{e2} and Ψ_{e3} are local electron-transfer “virtual” states.

this translates into an exponential dependence on donor–acceptor distance (the same is true for bent bridges, if an effective through-bridge distance is considered rather than the straight through-space one. Thus, Eq. 6 can also be used, in a phenomenological sense, to describe the distance dependence of donor–acceptor coupling through a modular bridge. The meaning of the various terms of Eq. 6 is seen by comparison with Eq. 9. In this case, r_0 is the length increment associated to the individual module, and $H_{if}^{el}(0) = (H_{i1}H_{nf})/\Delta E$ represents the donor–acceptor coupling for a one-module bridge. The attenuation factor $\beta = 2\ln(H_{12}/\Delta E)$ is a bridge-specific parameter depending on (i) the magnitude of the coupling between adjacent modules, and (ii) the energy of the electron- (or hole-) transfer states localized on each module. As described in detail in Chapter 1, the predicted exponential decay of the electronic coupling and the effects of (i) and (ii) have been verified in several homogeneous series of dyads containing modular organic bridges of variable length.

The above paragraphs underline the importance of the bridge in mediating donor–acceptor coupling. As a colloquial way to emphasize this role, it has become customary to consider bridges as “molecular wires”, to refer to their coupling ability as “conducting” properties, etc. It should be clear that these expressions, however used, are devoid of any real meaning. In the superexchange picture the bridge levels are always much higher in energy than those of donor and acceptor. In this mechanism, the electron tunnels in a single step from donor to acceptor, without being at any time localized on the bridge (in contrast to what happens for conduction along a wire). Real wire-like behavior, i.e., sequential donor-to-bridge and bridge-to-acceptor ET, can only be achieved when one of the electron transfer states involving the bridge is sufficiently low in energy as to become intermediate between the initial and final states (Figure 7). This is a rather uncommon situation, although it can be reached in special cases, using potent electron donors (e.g., singlet excited states of aromatic hydrocarbons) and highly conjugated bridges (e.g., *p*-phenylenevinylene oligomers) [22]. When wire-like conditions are reached, very small distance dependence of electron transfer rates is expected.

Figure 7. State diagram for a sequential donor-to-bridge-to-acceptor electron transfer (wire-like behavior).

The nuclear factor

The $FCWD^{el}$ term of Eq. 5 (often referred to as the “nuclear factor” of the rate constant) is a thermally averaged Franck–Condon factor connecting the initial and final states. It contains a sum of overlap integrals between the nuclear wavefunctions of reactant and product of the same energy. The nuclear wavefunctions include both (inner) vibrational modes and (outer) solvent reorganizational modes. The summation is made over the initial levels of the reactant, suitably weighted for their Boltzmann population. The expression of $FCWD^{el}$, which is quite complicated in a general case [10], becomes relatively simple in idealized situations. For example, in a simple approximation in which the solvent modes (average frequency, ν_o) are thermally excited and treated classically ($h\nu_o \ll k_B T$), and the internal vibrations (average frequency, ν_i) are frozen and treated quantum mechanically ($k_B T \ll h\nu_i$), and a single internal mode is assumed to be involved, the $FCWD^{el}$ term is given by Eq. 10 [10, 12].

$$FCWD^{el} = \left(\frac{1}{4\pi\lambda_o k_B T} \right)^{1/2} \sum_m S^m \frac{e^{-S}}{m!} \exp \left[-\frac{(\Delta G^\circ + \lambda_o + m h \nu_i)^2}{4\lambda_o k_B T} \right] \quad (10)$$

$$S = \frac{\lambda_i}{h \nu_i} \quad (11)$$

In Eq. 10, the summation extends over m , the number of quanta of the inner vibrational mode in the product state, ΔG° is the thermodynamic driving force of the process, S is the defined by Eq. 11, and λ_o is the outer-sphere (solvent) reorganizational energy, given in its simplest form [7–9] by

$$\lambda_o = e^2 \left(\frac{1}{2r_A} + \frac{1}{2r_B} - \frac{1}{r_{AB}} \right) \left(\frac{1}{D_{op}} - \frac{1}{D_s} \right) \quad (12)$$

where e is the electron charge, D_{op} and D_s are the optical and static dielectric constants of the solvent, r_A and r_B are the radii of the two molecular components, and r_{AB} is the intercomponent distance. In Eq. 11, λ_i is the inner-sphere (vibrational) reorganizational energy given, in the single mode approximation, by

$$\lambda_i = \frac{1}{2} k \Delta Q^2 \quad (13)$$

Figure 8. Energy profiles and kinetic parameters for an electron transfer reaction.

where k is an average force constant and ΔQ is the change in equilibrium geometry along the vibrational mode considered.

It can be shown [8] that in the high temperature limit (i.e., when $h\nu < k_B T$ for all relevant nuclear modes, an approximation not too inaccurate for many practical cases at room temperature), the nuclear factor takes the simple form

$$FCWD^{el} = \left(\frac{1}{4\pi\lambda k_B T} \right)^{1/2} \exp \left[-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda k_B T} \right] \quad (14)$$

where $\lambda = \lambda_i + \lambda_o$. The exponential term of Eq. 14 is the same as that predicted by the classical Marcus model [7–9], based on parabolic energy curves for reactants and products such as those of Figure 8, where the activation free energy is that required to go from the equilibrium geometry of the reactants to the crossing point. Both classical (Eq. 14) and quantum mechanical (Eq. 10) models contain an important prediction, namely, that three typical kinetic regimes exist, depending on the driving force of the electron transfer reaction: (i) a “normal” regime for small driving forces ($-\lambda < \Delta G^\circ < 0$) where the ET process is thermally activated and is favored by an increase in driving force; (ii) an “activationless” situation ($-\lambda \approx \Delta G^\circ$) where very small changes in rate are obtained by changing the driving force; (iii) an “inverted” regime for strongly exergonic reactions ($-\lambda > \Delta G^\circ$) where the ET process *slows down* with increasing driving force. Increasing λ slows down the process in the normal regime, but accelerates it in the inverted regime. The three

Figure 9. Free energy dependence of electron transfer rate (continuous line: classical treatment, Eq. 14; dotted line: quantum treatment, Eq. 10). The three kinetic regimes, “normal”, “activationless”, “inverted”, are shown schematically in terms of classical Marcus’ parabolae.

kinetic regimes are schematically shown, in terms of classical Marcus’ parabolae, in Figure 9. The main difference between the high-temperature limit expression (Eq. 14) and the quantum mechanical expression of $FCWD^{el}$ (Eq. 10) lies in the type of quantitative free-energy dependence predicted in the inverted region (Figure 9). The classical limit predicts a parabolic decrease of $\ln k_{el}$ with increasing driving force [7], as compared with a linear decrease (the so-called “energy-gap-law” of radiationless transitions) predicted for very negative ΔG values by the quantum mechanical models [10]. Definite proof for the existence of the inverted region has been reached in systematic studies of homogeneous series of reactions [23, 24].

Energy transfer

In a supramolecular system, electronic energy transfer (Figure 2) can be viewed as a radiationless transition between two “local” electronically excited states of the system (Eq. 15).

The rate constant for the energy transfer process is thus given by a “golden rule” expression similar to that seen above (Eq. 5) for electron transfer.

$$k_{en} = \frac{4\pi}{h} (H_{if}^{en})^2 FCWD^{en} \quad (16)$$

In Eq. 16, H_{if}^{en} is the electronic coupling between the two excited states interconverted by the energy transfer process, and $FCWD^{en}$ is an appropriate Franck–Condon factor.

As for ET, the Franck–Condon factor can be cast either in quantum mechanical [25–27] or in classical [28] terms. In quantum mechanical terms, this factor is a thermally-averaged sum of vibrational overlap integrals, representing the distribution of the transition probability over several isoenergetic “virtual transitions” (from *A to A , and from B to *B) in the two molecular components. Classically, it accounts for the combined effects of energy gradient and nuclear reorganization on the rate constant. In both cases, “normal” and “inverted” regions analogous to those found for ET transfer processes are predicted. In spite of some specific difficulties (e.g., highly exergonic processes are difficult to achieve, due to the presence of higher excited states of the products) experimental studies of Franck–Condon effects in energy transfer processes have been successfully carried out [29, 30].

The electronic factor H_{if}^{en} is a two-electron matrix element involving the HOMOs and LUMOs of the energy-donor and energy-acceptor centers. Following standard arguments [31], this factor can be split into additive *Coulombic* and *exchange* terms. The two terms depend differently on various parameters of the system (spin of ground and excited states, donor–acceptor distance, etc.). This leads to the identification of two main energy transfer mechanisms, as represented pictorially in Figure 10.

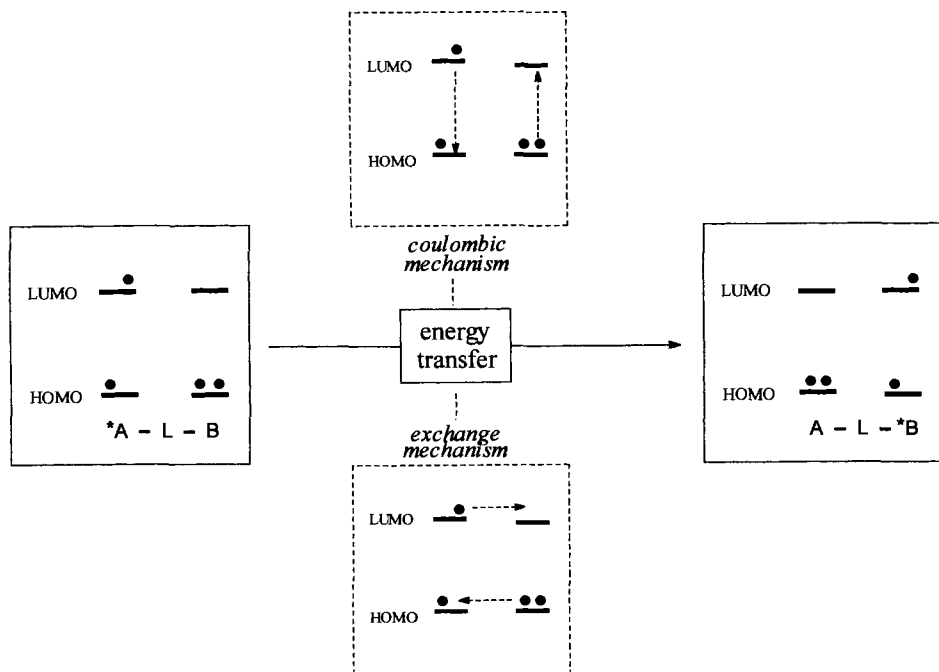

Figure 10. Pictorial representation of the Coulombic and exchange energy transfer mechanisms.

The Coulombic (also called “resonance”, “dipole–dipole”, or “Förster-type”) mechanism [32] is a long-range mechanism that does not require physical contact between donor and acceptor. The most important term within the Coulombic interaction is the dipole–dipole term, that obeys the same selection rules as the corresponding electric dipole transitions of the two partners (Figure 10). Therefore, Coulombic energy transfer is expected to be efficient in systems in which the radiative transitions connecting the ground and the excited state of each partner have high oscillator strength. The relationship between the rate constant for Coulombic energy transfer and the spectroscopic and photophysical properties of the two molecular components is given by the classical Förster formula (Eq. 17)

$$k_{en}^{coul} = 1.25 \times 10^{17} \frac{\Phi_A}{n^4 \tau_A r_{AB}^6} \int_0^\infty F_A(\bar{\nu}) \varepsilon_B \frac{d\bar{\nu}}{\bar{\nu}^4} \quad (17)$$

where Φ_A is the quantum yield of donor emission, n is the solvent refractive index, τ_A is the lifetime of the donor emission, and r_{AB} is the distance (in nm) between donor and acceptor. F_A is the emission spectrum of the donor (in wavenumbers and normalized to unity), and ε_B is the decadic molar extinction coefficient of the acceptor. With a good spectral overlap integral and appropriate photophysical parameters, the $(1/r_{AB}^6)$ distance dependence allows energy transfer to occur efficiently over distances (e.g., 50 Å), largely exceeding the molecular diameters. Coulombic energy transfer is therefore also called “long-range energy transfer”. The typical example of efficient coulombic mechanism is that of singlet–singlet energy transfer (Eq. 18)

In metal complexes, the only excited state of appreciable lifetime is generally the lowest, spin-forbidden excited state [33], so that Coulombic energy transfer is only expected to take place in then presence of very strong spin-orbit coupling (e.g., when 5d metal complexes are involved).

The *exchange* (also called “Dexter-type”) mechanism [32] is a short-range mechanism that requires orbital overlap, and therefore physical contact, between donor and acceptor. The exchange interaction can be visualized as the simultaneous exchange of two electrons between the donor and the acceptor (Figure 10). The spin selection rules for this type of mechanism reflect the need to obey spin conservation in the reacting pair as a whole. This allows the exchange mechanism to be operative in many cases in which the excited states involved are spin-forbidden in the spectroscopic sense. Thus, the typical example of efficient exchange mechanism is that of triplet–triplet energy transfer (Eq. 19).

Exchange energy transfer from the lowest spin forbidden excited state is expected to be the rule for metal complexes [34].

For reasons similar to those discussed above for ET processes, the rate constant of exchange energy transfer is expected to be sensitive to the nature of the bridge.

Using arguments similar to those of superexchange, mixing with electronically excited states localized on the bridge is expected to effectively mediate the donor–acceptor exchange interaction. Again, bridges with low-energy excited states will be particularly efficient. And again, if the electronically excited states localized on the bridge become lower in energy than that of the donor, a switch from direct one-step energy transfer to stepwise donor-to-bridge and bridge-to-acceptor energy migration could take place. With long, modular bridges, the exchange interaction is expected to fall off exponentially with through-bond distance, or with number of intervening units in the bridge [35–37]. Interestingly, in a homogeneous series of dyads where triplet energy transfer (Eq. 19), electron transfer (Eq. 20), and hole transfer (Eq. 21)

processes could be studied as a function of distance across the same saturated organic bridges, the value of the attenuation factor β (see Eq. 6) for energy transfer was found to be the sum of those for electron and hole transfer [38]. This supports the simple picture of exchange energy transfer as a “simultaneous double electron transfer”, with an electronic matrix element being proportional to the product of those for the corresponding electron and hole transfer processes.

3.1.4 Coordination Compounds as Molecular Components

As molecular components of a supramolecular system, coordination compounds display some peculiar features. A coordination compound is by definition a “complex” species, made by combination of metal and ligands. Although the ligands and (to some extent) the metal may exist separately as individual chemical species, they come into strong electronic interaction upon complex formation, leading to completely new characteristic properties. In other words, coordination compounds are not real supramolecular systems. Nevertheless, their complex nature is at the origin of some peculiar features, that may be relevant to their behavior as molecular components of dyads and larger covalently linked supramolecular systems. Some of these features can be discussed, taking the dyad of Figure 3 as an example.

The Ru(II)-based molecular component of the dyad in Figure 3 can be adequately modeled by $\text{Ru}(\text{bpy})_3^{2+}$, the archetypal chromophore of inorganic photochemistry [39, 40]. In $\text{Ru}(\text{bpy})_3^{2+}$, the HOMO is largely metal t_{2g} in character, while the LUMO is largely $\text{bpy } \pi^*$ in character. This predominant localization of the frontier orbitals has several interesting consequences. First, oxidation [$E^0(3+/2+) = 1.26$ V versus SCE] and reduction [$E^0(2+/+) = -1.28$ V versus SCE] of the unit involve different sites: $\text{Ru}(\text{bpy})_3^{3+}$ is a true Ru(III) complex, whereas the $\text{Ru}(\text{bpy})_3^{+}$ is not a Ru(I) species, but rather a Ru(II) complex with two neutral ligands and one ligand radical anion [41]. Second, the lowest excited states of $\text{Ru}(\text{bpy})_3^{2+}$ are of metal-to-ligand charge transfer (MLCT) character, with an electron distribution

resembling a Ru(III) complex with two neutral ligands and one ligand radical anion. Despite the presence of appreciable spin-orbit coupling, the MLCT states can be considered as having singlet or triplet spin multiplicity. The lowest singlet is responsible for the intense visible absorption (λ_{max} , 450 nm), while the lowest triplet is responsible for the characteristic phosphorescence emission (λ_{max} = 600 nm, E^{0-0} = 2.12 eV, Φ = 4×10^{-2} , τ = 0.6 μ s in room-temperature fluid solution). The relatively small singlet–triplet energy difference (c. 0.4 eV) is a consequence of the charge transfer nature of the transition. Within the triplet lifetime, fast equilibration between the three MLCT states localized on different ligands can be usually assumed [42]. The fractional population of such localized states (33 % in symmetric complexes such as Ru(bpy)₃²⁺) can be substantially unbalanced in less symmetric cases. In ligand-bridged bimetallic systems, a relevant question may be whether the predominant population is on the bridging ligand or on the ancillary ones. This depends on the relative LUMO energies (or redox potentials) of the three ligands. In the Ru(II) polypyridine unit of the dyad in Figure 3, because of the appreciable (albeit small) conjugation with the polyphenylene chain, the lowest energy site for the excited electron is definitely the bridging bipyridine.

For typical organic donor–acceptor systems, simple HOMO–LUMO pictures such as those of Figure 4 and 10 are often used to describe photoinduced electron or energy transfer. When coordination compounds are used as A and/or B molecular components, this type of picture might be overly simplistic given the peculiar localization of HOMOs and LUMOs. Figure 11a shows schematically the redox sites involved in MLCT excitation (process 1), photoinduced electron transfer (process 2) and charge recombination (process 3) for a typical Ru(II)–Rh(III) dyad. These localization aspects are likely to be important in the analysis of intramolecular electron transfer rates, where intercomponent distance and electronic coupling play a crucial role.

Similar arguments apply to the case of intercomponent energy transfer involving coordination compounds. In a Ru(II)–Os(II) dyad such as that of Figure 11b, exchange energy transfer following MLCT absorption the Ru(II) component (process 1) and leading to MLCT emission from the Os(II) component (process 3) can be visualized as two simultaneous cross-electron-transfer processes (processes 2): between the two bpy ends of the bridging ligand, and between the two metal centers. It should be noticed that, with short bridges such as that of the Ru(II)–Os(II) dyad of Figure 11c, what is formally (by analogy to the previous case) an intercomponent energy transfer phenomenon in fact amounts to a simple metal-to-metal electron transfer (process 2).

3.2 Bimetallic and Polymetallic Systems

A large number of covalently linked bi- and polymetallic systems have been synthesized and studied during the past 20 years. Early work has been reviewed, and a number of review articles are available [43–51]. The exhaustive review by Balzani

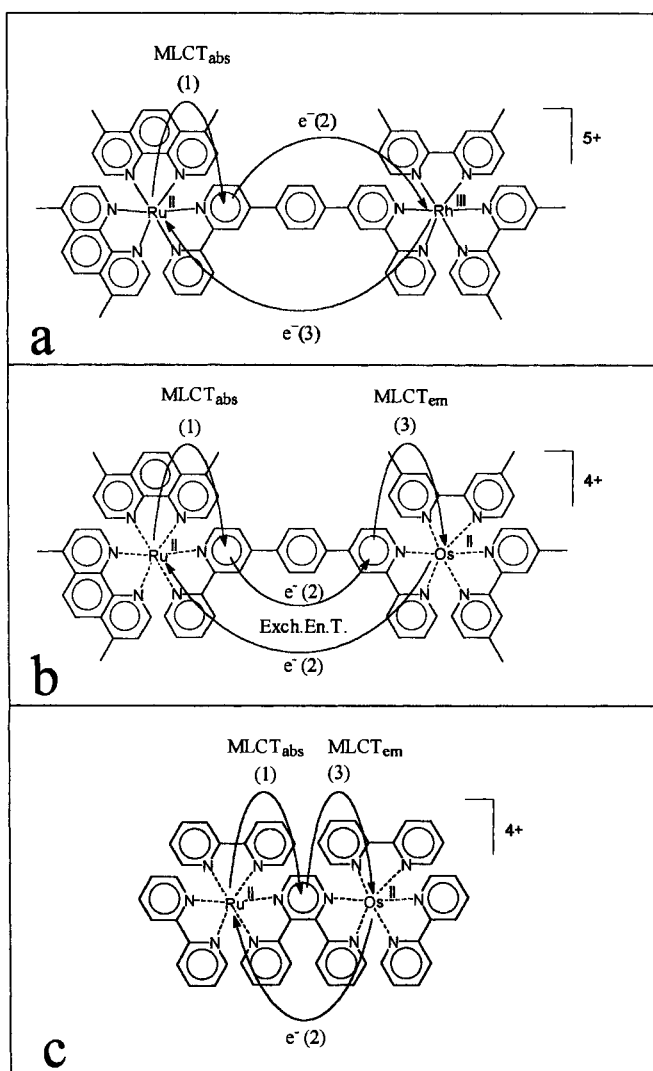

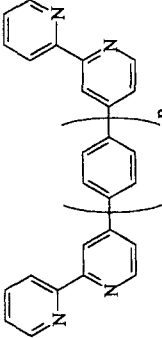

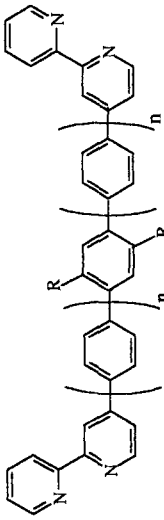

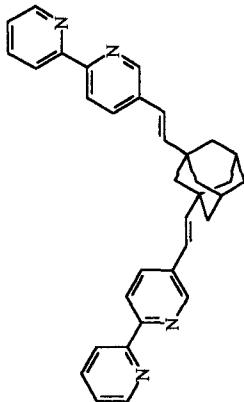

Figure 11. Schematic representation of the redox sites involved in photoinduced electron and energy transfer processes within dyads based on metal complexes.

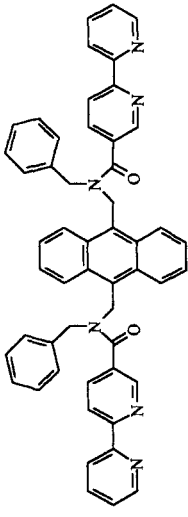

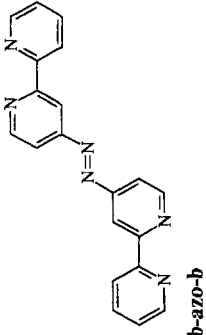

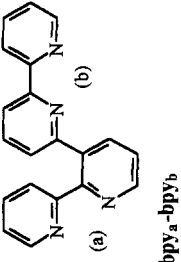

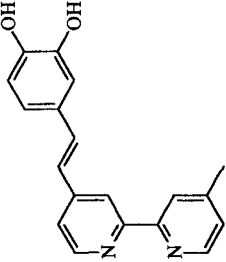

and coworkers provides complete literature coverage up to 1996 [47]. Some recent overview articles focus on specific classes of systems [48–51]. The field continues to grow at an impressive rate, and a representative selection of the bi- and polymetallic systems reported during the past four years (1996–1999) is summarized in Table 1. Since the emphasis of this chapter is on photoinduced energy and electron transfer processes, only unsymmetric systems (heterometallic complexes, homometallic complexes with the metals in different coordination environments) are included in Table 1. Two classes of bi- and polymetallic systems are deliberately excluded from the table. Cyano-bridged complexes [45, 48] are characterized by a strong metal–

metal electronic coupling; as a consequence, their behavior differs from that of the other ligand-bridged species in Table 1 in peculiar features such as intense intervalence transfer spectra [21, 52], and ultrafast energy [53] and electron transfer [54] processes. On the other hand, polymetallic systems of high nuclearity (≥ 4) and dendrimeric structure [55] are dealt with specifically in other chapters of this book.

In Table 1, the bi- and polymetallic complexes are grouped according to the bridging ligand, indicated by a structural formula, an appropriate abbreviation, and a reference number. Abbreviations for the ancillary (nonbridging) ligands can be found in Appendix I. The type of process observed for each system (when clearly identified by the authors) is included in Table 1. The acronyms are PET_{OX} and PET_{RED} for oxidative or reductive photoinduced electron transfer (Figure 1a,b), PCS for photoinduced charge shift (Figure 1c), and EnT for electronic energy transfer (Figure 2). The bimetallic dyads are always written so that the left-hand side metal identifies the initially excited chromophore (molecular component A in Figures 1 and 2). When necessary, footnotes are included to add further specifications.

Selected examples of bi- and polymetallic systems will be discussed in detail in subsequent sections.

3.3 Chromophore–Quencher Systems

Many interesting hybrid systems involve covalently linked inorganic and organic molecular components. The inorganic moiety usually plays the role of the light-absorbing chromophore (component A in Figures 1 and 2), while the organic component acts as the electron- or energy-transfer quencher (component B in Figures 1 and 2). Therefore, such systems are generally indicated as “chromophore–quencher” complexes. Early work has been reviewed [44], and recent work has been covered by Schanze in his extensive monograph [139].

In this section, representative examples of the chromophore–quencher systems that have appeared during the past few years (1996–1999) are referred to. The chromophoric units are almost invariably of the MLCT type, with Ru(II) and Re(I) polypyridine complexes being by far the most frequent cases. On the other hand, a great variety of organic quencher units have been used, and the same is true for the covalent linkage between the two types of unit. The chromophore–quencher systems, in contrast to the bi- and polymetallic ones, cannot be easily summarized in a tabular format. Rather, references will be briefly listed below, grouping the various chromophore–quencher systems according to the type of organic quencher unit. Selected examples will be described in more detail in subsequent sections.

3.3.1 Ferrocenes

Ferrocene is easily oxidized (E^0 , +0.49 V versus SCE) and has a relatively low-lying (c. 1.8 eV) very short-lived triplet state. Therefore, with many common chromo-

(1)

phores, ferrocenyl groups are good potential quencher units, with two mechanisms available: reductive PET (Figure 1a) and EnT (Figure 2). As a benchmark, for $\text{Ru}(\text{bpy})_3^{2+}$ and ferrocene, PET and EnT have comparable driving forces, being exergonic by c. 0.35 eV and c. 0.32 eV, respectively. In bimolecular quenching of $\text{Ru}(\text{bpy})_3^{2+}$ by ferrocene, the main process is EnT [140]. The preference for EnT over PET is probably related to the smaller reorganizational energy of the former process, as shown by the increasing amount of PET found when the driving force of this process is increased by using ferrocene derivatives of lower redox potential [140].

In the chromophore–quencher system (1) a ferrocenyl unit is connected to a $\text{Ru}(\text{tpy})_2^{2+}$ unit via a p -phenylene-acetylene spacer [141]. The weak emission of the $\text{Ru}(\text{tpy})_2^{2+}$ chromophore is completely quenched in the dyad [142]. For this system, an EnT mechanism could be inferred by analogy with the behavior of related bimolecular systems [140], but PET followed by fast back electron transfer cannot be ruled out. This mechanistic ambiguity is common to most studies on related chromophore–ferrocene dyads [143–146].

While for most chromophore–ferrocene dyads the photophysical behavior can be interpreted in terms of competing EnT and PET, additional complexities arise when the two units are connected by fully conjugated bridges (e.g., polyene chains). In fact, in such systems the lowest excited state may eventually become a Fe-to-bridge MLCT state [143].

3.3.2 Fullerenes

Fullerene (C_{60}) has low-lying excited states (S_1 , 1.94 eV; T_1 , 1.58 eV) [147], and is a good electron acceptor (first reduction at -0.35 V versus SCE, further reduction steps cathodically shifted by c. 0.53 V each) [148]. It is therefore a good candidate to act as a quencher, by both EnT (Figure 2) and oxidative PET (Figure 1b) mechanisms. A convenient feature from the viewpoint of experimental PET studies is the facile spectroscopic detection of fullerene radical anions. In fullerenes the reorganizational energy λ (Section 3.1.3) is small, as a consequence of the large molecular dimensions (λ_o) and the high degree of electron delocalization (λ_i). This is a positive kinetic feature towards the achievement of efficient and long-lived charge separa-

tion, as it is expected to accelerate the forward process (in the Marcus normal region) and to slow down charge recombination (in the Marcus inverted region). Because of these many interesting features, fullerenes have been recently used as molecular components in several kinds of supramolecular systems [149, 150]. Systems where fullerenes are covalently linked to porphyrins and other organic chromophores are dealt with in Volume III, Part 2, Chapters 1 and 2.

A number of dyads have recently been synthesized and studied, where a $\text{Ru}(\text{bpy})_3^{2+}$ chromophore is covalently linked to a fullerene derivative by bridges of various degrees of flexibility [151–154]. System (2) involves a rigid steroid-type spacer [153]. In acetonitrile, PET is exergonic by 0.24 eV and EnT by 0.47 eV. Despite its smaller driving force, PET is the primary process observed, with the charge separated state being formed in 0.2 ns. Interestingly, the charge recombination does not lead directly to the ground state (as, e.g., in Figure 1b), but rather the fullerene triplet is formed (in 100 ns) as an intermediate species.

3.3.3 Amines

Various types of amines have been used in chromophore–quencher systems for reductive PET (Figure 1a). Chromophore–quencher systems with aliphatic amines have often been used as potential luminescent chemosensors, for their pH-dependent quenching ability [155–157]. In some cases, the reductive PET can take advantage of irreversible (e.g., bond fragmentation) [158] or reversible (e.g., ring opening) [159] chemical reactions following formation of the amine radical cation. Dimethylaniline derivatives, with reduction potentials of c. 0.85 V versus SCE, have been used as attached groups to reductively quench $\text{Re}(\text{I})$ [160] and $\text{Ru}(\text{II})$ [161] polypyridine chromophores.

By far the most popular electron donor used in inorganic chromophore–quencher systems has been phenothiazine (PTZ). The pioneering studies of Meyer and co-workers [162, 163] on the chromophore–quencher complex (3) showed rapid (<10 ns) quenching of the MLCT excited state of the chromophore, with formation of a charge-separated state containing a reduced $\text{Re}(\text{I})$ complex (i.e., a $\text{Re}(\text{I})\text{-bpy}^{\bullet-}$ species) and the PTZ^+ radical cation. Charge recombination takes place in several tens of nanoseconds, with rates depending on the X-substituents. More recent work

on PTZ-containing dyads involves these systems with slightly different chromophores (e.g., bipyrimidine Re(I) systems) [164] or in heterogeneous environments (e.g., chemisorbed on SnO_2 [165], TiO_2 [166], SiO_2 [167]).

The PTZ unit has been widely used as the electron donor component in triad systems for photoinduced charge separation (see Section 3.4.5).

3.3.4 Pyridinium Ions

The most widely used electron acceptors in inorganic chromophore–quencher systems have been bipyridinium dications, often called “viologens” (quaternarized derivatives of 4,4′-bipyridine) or “diquat” (cyclic quaternarized derivatives of 2,2′-bipyridine). The classical studies of Elliott, Schmehl, and Mallouk have been concentrated on dyads of types (4) and (5). For dyads (4) [168, 169], oxidative PET takes place, with forward processes in the 80 to 1700-ps time scale and very fast (<30 ps) charge recombination. The main observations are that: (i) electron transfer to the diquat quencher occurs from the directly linked bipyridine ligand; (ii) fast equilibration between the MLCT excited states on the three bipyridine ligands precedes electron transfer; (iii) the electron transfer rates are in the “normal” Marcus

free-energy region and correlate accordingly with the driving force (depending on R and n); and (iv) the rates decrease exponentially with the number of methylene spacers, consistent with a through-bond ET mechanism. For dyads (5) [170, 171], both forward and back electron transfer rates could be measured. The back reaction depends on driving force as predicted for the Marcus inverted region. The rates of both processes decrease exponentially with the number of carbon atoms in the chain up to $m = 5$. After correction for the distance dependence of solvent reorganizational energy, the attenuation factor β is very similar for the two processes (1.0 – 1.2 \AA^{-1}). Dyads similar to (5), except for the presence of an amide linkage between the chromophore and the alkyl chain, have been studied by Kelly and Rodgers, with similar mechanistic conclusions [172]. A number of covalently linked systems containing various Ru(II) polypyridine complexes and various viologen-type quenchers (including the interesting 2,7-diazapyrenium unit) have been designed and studied by Balzani, Stoddart, and coworkers [173] in the context of their efforts towards light-driven pseudorataxane-type molecular machines (see Volume III, Part 2, Chapter 6).

Viologens have been used as covalently linked quenchers for Cu(I) bipyridine chromophores, leading to fast ($<10 \text{ ns}$) charge separation and remarkably slow (30 ns to $2 \text{ }\mu\text{s}$, depending on solvent) charge recombination [174]. More complex systems, similar to (5) but with two viologens on the same bipyridine of the Ru(II) chromophore, have been designed to mimic the presence of two ET in the reaction center of natural photosynthesis [175].

3.3.5 Other Systems

A variety of other quencher units have been recently used in inorganic chromophore–quencher systems. Electron acceptors include diimides [176, 177], quinones [178, 179], and nitroaromatics [180].

A number of interesting inorganic–organic dyads have been recently investigated that, rather than chromophore–quencher, could be called “chromophore–sensitizer”

systems. In fact, the appended units are high-energy dyes (coumarins) that transfer energy at the singlet level to Ru(II) polypyridine chromophore [181, 182].

3.4 Selected Topics

3.4.1 Electronic Energy Transfer in Bimetallic Systems: Ru(II)–Os(II) Dyads

Binuclear systems containing ruthenium(II) and osmium(II) complexes as active metal units represent by far the most extensively investigated class of compounds for the study of electronic energy transfer processes [50, 51]. An interesting series of Ru(II)–Os(II) polynuclear species of larger nuclearity containing 2,3-dpp and/or 2,5-dpp as bridging ligands, synthesized toward the development of artificial antenna systems [55], are dealt with in Volume 5, Part 1, Chapter 7.

In most of the dinuclear systems studied, the Ru-based and Os-based chromophoric components are tris-bipyridine or bis-terpyridine complexes connected by a large variety of bridging ligands (Table 1). For both metal components, the lowest excited states are triplet states of metal-to-ligand charge transfer (MLCT) nature. The Os(II) unit is easier to oxidize than Ru(II) unit, and thus the MLCT levels lie at higher energy in the Ru-based component than in the Os-based component. Therefore the Ru(II) units play the role of donor and the Os(II) units of acceptor in an intercomponent energy transfer process (Eq. 22). In a large number of cases both components are luminescent, so that the evidence for the occurrence of energy transfer has been generally obtained observing the quenching of the Ru-based luminescence and the sensitization of the Os-based luminescence.

In these systems the energy transfer process can occur by two mechanisms: the Förster-type mechanism (through-space); and the Dexter-type mechanism (through-bond). Very often these mechanisms occur competitively, and in some cases their relative contribution is difficult to evaluate. The method generally used to decide the type of mechanism is that of evaluating the rate constants (k_{en}^{F}) according to Förster treatment and compare the calculated values with the experimental ones [51]. It is important to note that, in this type of calculation, the values obtained are affected by large uncertainties in the input parameters. In particular, the choice of the appropriate value of the donor–acceptor distance is crucial. Uncertainties on this value can arise from: (i) flexibility of some of the bridges used; (ii) the MLCT nature of the excitation; and (iii) uncertainty on the localization of the MLCT excited state (in terms of the specific ligand involved). In Figure 12 the values of k_{en}^{F} for the couple $\text{Ru}(\text{bpy})_3^{2+}/\text{Os}(\text{bpy})_3^{2+}$ calculated according to Eq. 17 by using the spectroscopic quantities taken from Ref. [51] are plotted (continuous line) as a function of the separation distance between donor and acceptor (r_{AB}). The values calculated for the analogous couple $\text{Ru}(\text{tppy})_2^{2+}/\text{Os}(\text{tppy})_2^{2+}$ are practically identical. The values of the rate constants measured for some of Ru(II)–Os(II) dinuclear com-

Figure 12. Calculated k_{en} values (continuous line) according to Förster (Eq. 17), as a function of the metal–metal distance for the $\text{Ru}(\text{bpy})_3^{2+}/\text{Os}(\text{bpy})_3^{2+}$ couple. The parameters used are taken from Ref. [51]. Data points are experimental values for $\text{Ru}(\text{II})$ – $\text{Os}(\text{II})$ dyads, labeled according to the type of bridge (see Table 1): unsaturated bridges (\blacktriangle), aliphatic bridges (\blacksquare), bridges containing metal complex spacers (\bullet). The experimental values for the dyads labeled 3 are taken from M. Furue, T. Yoshidzumi, S. Kinoshita, T. Kushida, S. Nozakura, M. Kamachi, *Bull. Chem. Soc. Jpn.*, **1991**, 64, 1632.

plexes, designated by the labels of the bridging ligands used in Table 1, are collected in Figure 12.

The important observation is that the experimental values obtained for the systems with aliphatic bridging ligands (\blacksquare in Figure 12) are similar within one order of magnitude to the calculated k_{en}^F values. On the other hand, in the case of unsaturated bridges (containing aromatic and/or polyynes spacers; \blacktriangle in Figure 12), the energy transfer process was generally found to be relatively fast, with rate constants that are by far higher than the calculated k_{en}^F values (for the exception represented by the points 57; see below). This suggests that the Förster mechanism accounts for the observed energy transfer process in the case of aliphatic bridge, while the large electronic coupling between the donor and acceptor units provided by unsaturated spacers favors the Dexter mechanism. For some systems it seems reasonable to admit, however, that both mechanisms can play an important role. A significant example of substantial shift between the two types of mechanism is represented by the comparison between dinuclear complexes (6) and (7) (labeled 52 and 56 in Figure 12) investigated by Barigelletti and coworkers [124].

In the species containing two phenyl units as spacer (6) the high energy transfer rate constant is indicative of a Dexter through-bond mechanism. The interposition of a saturated group like bicyclo[2.2.2]octane (bco) between the two phenyls (7)

causes a dramatic decrease in the energy transfer rate. The authors conclude that this effect cannot be simply accounted for by the increased intermetal distance ($d = 20 \text{ \AA}$ and 24 \AA for the complexes (6) and (7) respectively), but a major role must be ascribed to the electronically insulating properties of the bco saturated group. Actually, in system (7) the energy transfer rate constant has dropped to a value close to the calculated Förster value.

In some cases structural effects could give indications about the type of mechanism. Ziessel et al. [49, 103] have used the Pt^{II} bis- σ -acetylide spacer to construct two isomeric binuclear complexes, *cis* (8) and *trans* (9) forms, with different metal-to-

metal distance between the Ru-based and Os-based chromophoric units ($d_{M-M} = 13.7 \text{ \AA}$ and 19.2 \AA for *cis* and *trans* isomers, respectively). In the *cis* complex, because of shorter metal-to-metal distance, faster energy transfer via Förster mechanism is expected, while similar energy transfer rate constants for the two isomers could be expected for a Dexter mechanism given the same through-bond length. Experimentally, the energy transfer process was found to occur slightly slower for the *cis* isomer than for the *trans* analogue. This result is interpreted by the authors as due to the fact that both mechanisms are operative and their relative contribution to the overall energy transfer process is different for the two isomers: the energy transfer in the *cis* isomer is dominated by Coulombic interactions, while the electron exchange is the preferred mechanism for the *trans* complex where the stereochemistry of the bridge increases the orbital overlapping and therefore favors the electronic coupling between the donor and acceptor units.

From a close inspection of Figure 12, the data points labeled 57 appear to be anomalous with respect to the other triangle data points, i.e., if compared with the values obtained for the other dyads containing unsaturated bridges. These points correspond to systems where the two metal units are connected by cyclometalated bridging ligand [124, 130], e.g., dyad (10). In such a system, the Ru \rightarrow Os energy transfer process is much slower ($k < 2 \times 10^7 \text{ s}^{-1}$) with respect to the case of system (6) (labeled 52 in Figure 12; $k = 5 \times 10^{10} \text{ s}^{-1}$), despite the fact that the two systems contain the same diphenylene spacer. The reason for this behavior is the different localization of MLCT states involved in the transfer process: in (6) the MLCT excited states involve the bridge, while in (10) the MLCT states are localized on the terminal ligands and therefore in the latter case, the energy transfer pathway is longer. This result highlights the crucial role of localization aspects in determining the energy transfer rate.

In energy as well as in electron transfer processes, an important issue is the distance dependence of the rate constant. It is important to note that in the case of energy transfer in polynuclear complexes systematic studies are performed only in very few cases. The series of the binuclear complexes (11) ($n = 1, 2, 3$) investigated by Balzani and coworkers [65], represent an excellent example of systems particularly suited for this type of study because the modular composition of oligophenylene spacer allows changing the metal-to-metal distance in a systematic way. The important result is that in these systems the energy transfer process is highly efficient, even for a distance of 42 Å, indicating that the oligophenylene bridge behaves as a good energy transducer. The rate constant has been found to decrease exponentially with increasing the metal-metal distance and an attenuation coefficient (β) of 0.32 Å^{-1} has been obtained.

For the series of complexes (12) ($n = 1, 2$) containing alkyne spacers, Harriman and Ziessel have estimated an attenuation factor of the order of 0.17 Å^{-1} [106, 127]. This relatively small value indicates that through alkyne bridges the “electronic conduction” for energy transfer is more efficient with respect to the polyphenylene counterparts.

Ziessel et al. have explored extensively the possibility of controlling and modulating the electronic properties of a bridge by incorporating additional unit into the unsaturated polyacetylenic backbone [49]. An elegant example that illustrates this point is represented by a series of Ru-Os binuclear complexes where the polyacetylenic bridge contain a phenyl (13), a naphthyl (14), and an anthryl (15) group, respectively.

Along this series, the energy of both HOMOs and LUMOs resident on the bridge decreases with the increasing size and conjugation of the polycycle. The power of

this approach is demonstrated by the results of the photophysical investigation, which clearly indicate that the energy of the polycyclic unit causes a profound effect on both rate and pathway of the energy transfer process (Figure 13). For the phenyl-bridged complex (13), where the triplet of the bridge is higher in energy than that of the donor, an exchange energy transfer process takes place directly from the Ru-based to Os-based metal units. In the naphthyl-bridged Ru-Os system (14), where the triplet of the bridge is between the triplet of the Ru-based and Os-based units, the energy transfer occurs in a stepwise manner: first to the central naphthalene unit of the bridge and then to the terminal Os-based fragment. In the anthryl-bridged system (15), the triplet of the bridge is lower than those of both metal components and rapid energy transfer processes from both metal units to the bridging anthryl group were observed. Decreasing the energy of the triplet of the

Figure 13. Schematic energy-level diagram for aryl-bridged Ru(II)-Os(II) dyads.

polycyclic unit causes its direct participation in the energy-transfer sequence until, as in the case of anthracene, the bridge becomes a trap.

3.4.2 Photoinduced Electron Transfer in Bimetallic Systems: Ru(II)-Rh(III) dyads

A dyad for oxidative PET (Figure 1b) contains a photoexcitable donor (A) and an electron acceptor (B) that, for ideal performance, should fulfil a rather stringent set of conditions.

(16)

For practical purposes (using visible light, achieving selective excitation), A should feature low-energy intense absorption (i.e., be a visible chromophore). Also intrinsic to the function of A is that it have a strong excited-state reducing character. These two conditions automatically limit the magnitude of the ground-state oxidation potential, as E^{0-0} , $E^0(\text{A}^+/\text{*A})$, and $E^0(\text{A}^+/\text{A})$ are mutually related (Eq. 3). Additional useful features include a relatively long excited state lifetime (to support relatively slow ET processes), and that it have easily detectable emission (for facile excited-state monitoring). A good compromise between all these requisites is achieved by complexes of the Ru(II) polypyridine family (although other d^6 systems such as Re(I) and Os(II) also have interesting properties). Using $\text{Ru}(\text{Me}_2\text{phen})_2(\text{Me}_2\text{bpy})^{2+}$ (**16**) as a paradigmatic case, the relevant properties are $E^{0-0} = 2.16$ eV, $E^0(\text{A}^+/\text{*A}) = -1.02$ V, $E^0(\text{A}^+/\text{A}) = 1.14$ V versus SCE, $\lambda_{\text{max}}^{\text{em}} = 610$ nm, $\Phi = 0.11$, $\tau = 1.8$ μs [183].

The B component must also meet a set of specific requirements. First, it must be practically nonchromophoric (so as to avoid interference with excitation light absorption by A), and second, it should be a good ground-state electron acceptor [$E^0(\text{B}/\text{B}^-) > E^0(\text{A}^+/\text{*A})$]. It should also have a lack of low-energy excited states [$E^{0-0}(\text{*B}) > E^{0-0}(\text{*A})$, in order to avoid EnT quenching], and also be kinetically stable in the reduced B^- form (at least in the time scale of the charge recombination process). Among metal polypyridine complexes, the choice for good electron acceptors is practically limited to a number of trivalent metal systems. Few of these systems, however, are actually suitable. In 3d metals, e.g., Co(III), Cr(III), low-energy ligand-field states are present. Moreover, in some cases, e.g., Co(III), the reduced forms are highly labile. Most of the above requirements are met, on the other hand, by d^5 systems such as, e.g., Os(III). Oxidative PET has indeed been studied in a number of Ru(II)–Os(III) polypyridine dyads [66, 76–78, 90, 129]. In all these systems, however, the reduction of the acceptor unit is so facile (e.g., for $\text{Os}(\text{bpy})_3^{3+}$, $E^0(\text{III}/\text{II}) = 0.78$ V versus SCE) that almost all of the excited-state energy is wasted in the forward process, and very little is stored transiently in the charge-separated products. A more attractive situation is found using Rh(III) polypyridine complexes as acceptor units. Taking $\text{Rh}(\text{Me}_2\text{bpy})_3^{3+}$ (**17**) as a paradigmatic case for this class of molecular components, relevant properties are: $E^{0-0} = 2.77$ eV, $E^0(\text{B}/\text{B}^-) = -0.89$ V versus SCE, $\tau = 3$ ns [183]. The kinetic lability of the Rh(II) species—which could be a drawback for long time scale experiments

(17)

(milliseconds)—is irrelevant to the fast, reversible PET processes taking place within the dyads.

A number of Ru(II)–Rh(III) polypyridine dyads have been synthesized and studied during the past few years [60, 63, 117, 121, 122, 183]. The mechanistic aspects of such studies are discussed in some detail in this section.

Energetics and general behavior

The general properties of Ru(II)–Rh(III) polypyridine dyads can be discussed taking dyad (18) as an example [183]. The absorption spectrum of dyad (18), as compared with those of suitable models of the molecular components, (16) and (17), is shown in Figure 14. This shows that the spectra of the molecular components are strictly additive, as expected for weak intercomponent interaction. It also shows that selective (100 %) excitation of the Ru(II) chromophore can be easily performed in the visible region, whereas partial excitation of the Rh(III) component (c. 70 % at 300 nm) can be achieved in the ultraviolet (where overlapping ligand-centered (LC) bands of both molecular components are observed). The energy level diagram for this dyad is shown in Figure 15. Indicated are the common photophysical processes taking place within each molecular components, i.e., prompt intersystem crossing to form the long-lived triplet states. Also indicated are a number of thermodynamically allowed intercomponent processes, including:

(18)

Figure 14. Absorption spectra of Ru(II)–Rh(III) dyad (dotted line, c), Ru(II) model (dashed line, b), and Rh(III) model (continuous line, a).

Figure 15. Energy level diagram of the Ru(II)–Rh(III) dyad (18).

Figure 16. Plot of $\log k$ versus ΔG° for the three electron transfer processes of dyad (**18**).

- | | |
|---|--|
| (a) $^*\text{Ru(II)}-\text{Rh(III)} \rightarrow \text{Ru(III)}-\text{Rh(II)}$ | oxidative quenching of the excited Ru(II) |
| (b) $\text{Ru(II)}-^*\text{Rh(III)} \rightarrow \text{Ru(III)}-\text{Rh(II)}$ | reductive quenching of the excited Rh(III) |
| (c) $\text{Ru(II)}-^*\text{Rh(III)} \rightarrow ^*\text{Ru(II)}-\text{Rh(III)}$ | EnT from Rh(III) to Ru(II) |
| (d) $\text{Ru(III)}-\text{Rh(II)} \rightarrow \text{Ru(II)}-\text{Rh(III)}$ | charge recombination |

For dyad (**18**), all these processes could be time-resolved under the appropriate experimental conditions (visible excitation for *a*, UV excitation for *b* and *d*, rigid matrix for *c*), leading to the detailed kinetic picture of Figure 15 [183]. The widely different rates of the three ET processes (*a*, *b*, *d*) can be rationalized in terms of predominant driving force effects, as shown schematically in Figure 16 (although more subtle effects of electronic factors cannot be ruled out; see Section 3.1.4 and Figure 11a).

Bridge and distance effects

In subsequent studies of Ru(II)–Rh(III) polypyridine dyads, the chromophoric and acceptor units were of the tris-bipyridine (or phenanthroline) type [63] or of the bis-terpyridine type [121, 122], whereas the bridges were based on *p*-phenylene spacers (Scheme I). With these rod-like, longitudinally rigid dyads, attention was focused on the slightly exergonic oxidative quenching following Ru(II) excitation (process *a* in Figure 15), and the emphasis was placed on the study of bridge and distance effects. In analyzing the results of these studies, it should be borne in mind that the energetics of PET (see, e.g., Figure 15) is practically the same for the bpy (or phen) complexes and for the tpy ones. The rate constants reported in Scheme I indicate, as expected, a general decrease of electron transfer rates with increasing bridge length. The following observations are worth of comment.

A comparison between dyad (**18**) and dyad (**21**) demonstrates that the phenylene group is a better “conducting” spacer (see Section 3.1.3 for a caveat on this colloquial terminology, however) as compared to methylene: despite the longer metal–metal distance, the reaction is faster across the phenylene spacer ($k = 3.0 \times 10^9 \text{ s}^{-1}$)

Scheme I

than across the methylene one ($k = 1.7 \times 10^8 \text{ s}^{-1}$). This is no doubt related to the lower energy of the LUMO of the phenylene group, facilitating superexchange interaction (Eq. 7).

Dyads (19) and (21), despite the vast difference (three orders of magnitude) in lifetimes of the chromophores involved, give identical PET rates. This is experimentally gratifying and confirms that the energetics of PET (see, e.g., Figure 15) is practically the same for dyads of the bpy (or phen) and tpy families.

Figure 17. Distance dependence of forward electron transfer rates in dyads (21), (22), (24) (circles) and (23) (squares).

The rate constants for PET of dyads (21)–(24) are displayed on a logarithmic plot as a function of the metal–metal distance in Figure 17. It can be seen that the three systems with unsubstituted polyphenylene spacers exhibit a nice exponential dependence of rates on distance. This is the behavior predicted by Eqs. 5 and 6 on the basis of the exponential decay of the electronic factor H_{AB} , if the distance dependence of the FCWD term can be neglected. From this viewpoint, a nice feature of the Ru(II)–Rh(III) dyads is the charge-shift nature of the process (PET leads from a $2+/3+$ to a $3+/2+$ species). Thus, in contrast to typical organic dyads (where a pair of opposite charges is created in the PET process), the two Coulombic terms in Eq. 3 exactly cancel out, and the driving force is independent on the donor–acceptor distance. This eliminates one of the two possible causes of distance dependence of the FCWD term. The remaining one is λ_o , expected to increase slightly with distance (Eq. 12). Its contribution to the observed rate decrease is presumably relatively small, but is difficult to evaluate exactly as it depends on the assumed partitioning of λ into λ_i and λ_o . Therefore, the β value obtained from the slope of the line in Figure 17 (0.5 \AA^{-1}) should be regarded as an upper limiting value for the attenuation factor of the intercomponent electronic coupling (Eq. 6). This value is much lower than those observed for rigid saturated bridges ($0.8\text{--}1.2 \text{ \AA}^{-1}$) [15, 184–186], and similar to that obtained for electron transfer between porphyrins across oligophenylene spacers [187].

Of particular interest is the fact that dyad (23), which is identical to dyad (24) except for the presence of two solubilizing hexyl groups on the central phenylene ring, undergoes PET c. 50 times slower than its unsubstituted analogue. This is most likely related to the notion that electronic coupling through a polyphenylene spacer is a sensitive function of the twist angle between adjacent spacers [188, 189]. Such twist angle is presumably c. 45° for unsubstituted adjacent phenylene rings (as in biphenyl). It is expected to increase, however, in the presence of alkyl substituents. Assuming a cosine angle dependence for adjacent coupling terms (e.g., H_{12} and H_{23} in Eq. 8 and Figure 6), an increase in twist angle upon substitution from c. 45° to c. 75° would be sufficient to account for the observed rate decrease.

The study of the Ru(II)–Rh(III) dyads in Scheme I has shown that rigid polyphenylene bridges are efficient mediators of long-distance PET. Coupled with the

(25)

long lifetime of the excited Ru(II) chromophore, such bridges could (in principle) sustain PET over very long distances (e.g., extrapolating from Figure 17, ≥ 40 Å). In principle, the dependence of the electronic coupling on the inter-spacer twist angle could be used for tuning or switching purposes.

3.4.3 Reversible Energy Transfer in Systems with Aromatic Hydrocarbon Units

Chromophore–quencher systems where the organic molecular components are aryl hydrocarbons are under intense study [67, 190–205]. In these systems an inorganic moiety (based on polypyridine complexes of Ru(II), Os(II), Re(I)) and an aryl hydrocarbon (naphthalene, anthracene, pyrene) are covalently linked by flexible aliphatic [187–201] or rigid conjugated bridges [49, 190, 191, 193].

In dyads formed by the Ru(bpy)₃²⁺ complex and an anthracene moiety (**25**), a strong quenching of the MLCT luminescence of the Ru-based unit is observed [195]. This quenching is attributed to exergonic triplet–triplet energy transfer from the metal complex to anthracene. The process, in which anthracene acts as an EnT quencher, is represented in Figure 18. A similar behavior has been observed in a dyad formed by a Re(bpy)(CO)₃ unit and an anthracene moiety [202].

When the aryl linked to the Ru(bpy)₃²⁺ unit is a pyrene (**26**), an enhancement (from about 1 μs to 11.2 μs) of the MLCT lifetime is observed [204]. This result is interpreted on the basis of a reversible energy transfer mechanism implying equilibrium between the MLCT and aromatic triplet states which are very close in energy (Figure 18). This effect is confirmed by Wilson et al. [196] in an elegant study of a family of dyads formed by the Ru(bpy)₃²⁺ unit and pendant naphthalene, pyrene, or anthracene. The photophysical properties of each dyad are determined by intramolecular energy transfer processes that are governed by the relative position of the various triplet energy levels: the initial excitation energy is localized respectively on the MLCT state for Ru-naphthalene and on the anthracene triplet for the Ru-anthracene. Since the Ru-based MLCT and the lowest pyrene triplet state are almost isoenergetic, an equilibrium is established resulting in a long-lived lifetime for the Ru-pyrene (5.3 μs) [196].

(26)

The reversible triplet energy transfer between MLCT and a long-lived, almost isoenergetic triplet state of aryl moieties suggests an interesting strategy for extending the triplet lifetime of the metal complex fragment. This new approach seems to be more effective in improving the photophysical properties of these chromophores than the traditional ones based on using rigid matrices or on rising the triplet energy (energy gap law).

A dramatic effect of the reversible energy transfer mechanism has been obtained by Harriman, Zissel and coworkers [49, 190, 191, 193] in a family of dyads where the metal complexes (Ru(II) or Os(II)-based) are connected to the aryl unit by an alkyne connector, which is known to promote strong, directional electronic coupling. In particular, the results show that in a dyad formed by a $\text{Ru}(\text{bpy})_3^{2+}$ [190, 191] fragment linked by the ethynyl bridge to pyrene, the lifetime of the MLCT triplet state increases 40-fold with respect to that of the parent complex (i.e., from 1.4 μs to 40 μs) [191]. The prolongation of the triplet lifetime is consistent with MLCT being in equilibrium with the triplet associated to the pyrene unit which is situated at slightly lower energy and reflects both the low percentage of the MLCT triplet present in the equilibrium mixture and the relatively long inherent lifetime of the pyrene units [191].

The same study [191] shows that the extremely short lifetime ($\tau < 1$ ns) of the chromophore $\text{Ru}(\text{tpy})_2^{2+}$ can be effectively enhanced by attaching an ethynylated pyrene. In the related dyad containing pyrene and $\text{Ru}(\text{tpy})_2^{2+}$, the lifetime of the $\text{Ru}(\text{tpy})$ fragment ($\tau = 570$ ns) greatly exceeds that recorded for any other ethynylated mononuclear $\text{Ru}(\text{tpy})$ fragment ($\tau = 50$ ns) [49]. In this case, prolongation of the MLCT triplet lifetime cannot be explained only in terms of reversible triplet energy transfer, since the pyrene triplet state energy is slightly higher than the MLCT of the metal complex. The authors attribute the extra stabilization of the MLCT to mixing between the MLCT triplet and the pyrene like $\pi-\pi^*$ triplet [191].

An analogous mechanism of reversible energy transfer is operative in a dyad where an $\text{Os}(\text{bpy})_3^{2+}$ unit is connected to an anthracene system by an ethynyl bridge: the lifetime of the $\text{Os}(\text{II})(\text{bpy})$ fragment ($\tau = 420$ ns) is almost ten times longer than that of the parent complex ($\tau = 60$ ns) [193].

Figure 18. Schematic energy-level diagrams and photophysical processes for Ru(bpy)₃²⁺-aryl dyads.

The mechanism of reversible triplet–triplet energy transfer is used in a light-harvesting array constructed around a the $\text{Ru}(\text{bpy})_3^{2+}$ core and bearing one or three pyrenyl units in the periphery (27) [192]. UV excitation of these systems yields a strong visible MLCT-based emission, with a lifetime of 2.9 and 9.0 μs respectively for the mono- and the tris-pyrene system. The equilibrium constant between the MLCT and the pyrene triplet, and therefore the triplet lifetimes, are modulated by the fractional contribution of each individual triplet molecule involved in the equilibrium. This approach allows for a synthetic control of the luminescence lifetime by simply changing the number of pyrenyl units.

3.4.4 Photoinduced Charge Shift in Chromophore–Quencher Systems

One of the available ways for investigating intramolecular electron transfer is that of inducing a charge shift by bimolecular PET (Figure 1c). The feasibility of this relies on the fact that the bimolecular event producing the thermodynamically unfavored electronic isomer of the dyad is faster than the intramolecular electron transfer process to be observed. When this requirement is met, since the back recombination reaction is a bimolecular process, relatively slow intramolecular electron transfer processes can be studied. This type of process has been extensively used for studying electron transfer in proteins [206], but has not been frequently applied to dyads. In an early study [207], the $\text{Rh}(\text{III})$ –diquat dyad (28) was

quenched reductively by trimethoxybenzene. The primary product, Rh(II)-diquat, was shown to undergo intramolecular ET to Rh(III)-diquat^{•-} with a rate constant of $3 \times 10^7 \text{ s}^{-1}$. This figure is consistent with PET rates obtained with similar bridges and driving forces, e.g., in (18).

An example of intramolecular charge shift initiated by oxidative bimolecular quenching is that of the Ru(II)-phenothiazine dyad (29) [208]. Quenching of the excited Ru(II) chromophore by methylviologen gives Ru(III)-phenothiazine as primary product. In this primary product, intramolecular ET takes place in 170 ns to yield Ru(II)-phenothiazine^{•+}.

In a series of papers [61, 209], photoinduced charge shift has been used by Hammarström and coworkers to mimic some aspects of the oxygen-evolving part of photosystem II, where the photo-oxidized chlorophyll dimer, P_{680}^+ , is reduced by electron transfer from a nearby manganese cluster, mediated by a tyrosyl group. The dyads used were of type (30) and (31), including a Ru(II) complex as photo-excitable chromophore and a Mn(II) complex or a tyrosine group as electron donors. The acceptors in the bimolecular PET step were methyl viologen or Co(III). Charge shift from the Mn(II) complex [61] or from the tyrosine [209] to the photo-oxidized

Ru(III) center was observed, with rate constants of the order of 10^5 s^{-1} . Related model systems, mimicking the interactions between the tyrosine and other residues, have also been studied [209].

Some complex model systems, incorporating a Ru(II) photoexcitable unit and both phenolate and manganese complexes, have recently been produced by Wiegardt and coworkers [115, 210]. One such model, involving a mononuclear Mn(IV) species, is the tetranuclear species (32) [115]. In the presence of methylviologen, the usual charge shift from the phenolate to the photo-oxidized Ru(III) center takes place, although the mechanism is complicated by the possibility of direct oxidative intramolecular PET. Even more complex models based on similar design, but containing a trinuclear Mn(II) species acting as the electron source for intramolecular oxidative PET, have been developed [115].

3.4.5 Multi-Step Charge Separation in Triads

In principle, the photoinduced charge separation obtained in dyads offers a potential route for the conversion of light energy into chemical energy. To that purpose,

(32)

the charge-separated products of PET should react with appropriate substrates to yield high-energy, kinetically stable products (fuels). From this viewpoint, however, dyads are of little practical use because of the occurrence of the back electron transfer reaction (Figure 1a,b). This charge recombination process is usually quite fast, whereas the reactions to be performed on the substrate are inevitably multi-electron, and thus intrinsically slow processes. The reactions involved in water splitting are given, as an example, in Eqs. 23 and 24.

A strategy to overcome this problem—largely inspired by the architecture of natural photosynthetic reaction centers—is that of going from dyads to more complex supramolecular systems in which a sequence of electron transfer steps is used to achieve charge separation. In such systems, charge recombination must take place between spatially remote sites and is thus expected to be substantially slowed down. The simplest of such system is a *triad*, as illustrated schematically in Figure 19 for two possible schemes. In Figure 19a, the two consecutive ET steps are (1) from the excited chromophore, P, to an acceptor molecular component, A, and (2) from a donor unit, D, to the oxidized chromophore. In Figure 19b, the two consecutive electron transfer steps are (1) from the excited chromophore, P, to a primary ac-

Figure 19. Two types of triads for photoinduced charge separation. Molecular components are designated as: P (chromophore); D (donor); A (acceptor); A' (secondary acceptor). Electron transfer processes are designated as: *cs* (primary PET); *cr* (primary charge recombination); *cs'* (secondary charge separation); *cr'* (final charge recombination).

ceptor, A, and (2) from the primary to a secondary acceptor unit, A'. In both cases, the yield of charge separation is given by

$$\Phi_{cs} = \frac{k_{cs}}{k_{cs} + (1/\tau)k_{cs'} + k_{cr}} \quad (25)$$

while the lifetime of the charge separated state is simply $1/k_{cr'}$. Of the two terms in Eq. 25, the first one (efficiency of quenching of the excited chromophore) is easily maximized, especially with intrinsically long-lived chromophores such as e.g., Ru(II) polypyridine complexes. In fact, the key to efficient stepwise charge separation lies in the second term of Eq. 25, i.e., in the competition between primary charge recombination, k_{cr} , and secondary ET process, $k_{cs'}$.

Several triads (as well as more complex systems, tetrads, pentads, etc.) have been successfully developed making use of organic molecular components [211–213], some of which (porphyrins, quinones, carotenoids) are reminiscent of those found in the natural systems (for detailed accounts, see Volume III, Part 2, Chapters 1 and 2). Remarkable efficiencies and lifetimes of charge separation have been reached with such systems. Their potential has been impressively demonstrated by incorporation into liposomal membranes performing the photo-driven synthesis of ATP [214].

A number of triads have also been designed and studied in which at least one of the molecular components—usually the light-absorbing chromophore—is a transition metal coordination compound. Acceptor molecular components are often viologens or quinones, while donor molecular components are most often phenothiazine units or amine units. Some representative examples are given in Figures 20 and 21. As a prototype system, let us consider that of Figure 20a, extensively studied by Meyer and coworkers [215, 216] (related systems containing cyclic 2,2'-bipyridinium units (diquat) were studied by Elliott and coworkers [217, 218]). With $X = X' = \text{CH}_3$, the system behaves as in Figure 19a, where *cs* and *cs'* are faster than 5 ns, whereas the charge-separated state recombines (*cr'*) in a time scale of 100–200 ns. A detailed study, in which all the four positional isomers (donor and acceptor groups in one *trans* and three *cis* positions) were separately investigated, yielded slightly different rates for different isomers. The yield of formation of the charge-separated $\text{PTZ}^{\bullet+}\text{-Ru(II)-MV}^{\bullet+}$ was 0.20–0.25 [215]. With $X = \text{COOH}$ and $X' = \text{CH}_3$, the slightly different energetics improves the charge separation yield by making both *cr* and *cs'* (Figure 19a) more exergonic than in the previous case. Since *cr* is in the inverted region and *cs'* in the normal one, the former process is slowed down, while the latter is accelerated [216].

The triad of Figure 20b, based on the Ru(II) bis terpyridine chromophore with intrinsic *trans* geometry, has been developed by Sauvage and coworkers [219]. The system in Figure 20c is an example of triads containing an anthraquinone group as acceptor [220, 221]. The system of Figure 20d is actually a tetrad, including two identical chromophores connected by an ethylenic bridge, one carrying a donor (PTZ) and one carrying an acceptor (of the monoquat type) [222]. The two triads of Figure 21a,b involve similar molecular components as some of the previously considered ones, but the connecting scheme is different [223, 224]. Here, the chromophore, the donor, and the acceptor units are all covalently connected to a central lysine unit. The strategy of using amide linkages for connecting molecular components to amino acids has been recently extended by Meyer to the construction of triad systems on helical proline oligomers used as a scaffold [225].

Relatively different molecular components have been used by Ziessel et al. [226] in the construction of triad (33), where the donor is the *p*-(diethylamino)-styryl group, and the acceptor is the 4-pyridyl-3,8-dimethyl-1,3,5,7,9-decapentaenyl group. A remarkably long-lived transient (4 μs) is attributed to the charge separated state.

3.5 Concluding Remarks

This review is not intended to provide an exhaustive picture of photoinduced electron (and energy) transfer in covalently linked inorganic systems. It should demonstrate, however, that this is an active and attractive field of research. Coordination compounds, because of their intrinsic combinatorial nature, offer wide possibilities in terms of tailoring spectroscopic, redox, and photophysical properties of molecular components. The continuing progress in chemical synthesis provides a variety of

Figure 20. Various types of systems for stepwise charge separation containing inorganic chromophores and organic donor-acceptor units.

Figure 21. Two triads with inorganic chromophore and organic donor-acceptor units built around a central lysine core.

intercomponent connecting motifs and permits the rational design of supramolecular structures with the desired organization of molecular components in the dimensions of space and energy. For basic studies of electron (and energy) transfer kinetics and mechanisms, covalently linked inorganic systems may offer some advantages with respect to their organic analogues, especially in terms of easily tunable redox properties and long excited state lifetimes. In a more perspective view of supramolecular chemistry, covalently linked inorganic systems can be considered as useful tools towards the construction of devices for energy conversion, sensing, signaling, and information processing and storage at the molecular level.

4 Electron Transfer in Hydrogen-Bonded Donor–Acceptor Supramolecules

Christopher J. Chang, Joshua D. K. Brown, Michelle C. Y. Chang, Erin A. Baker and Daniel G. Nocera

4.1 Introduction

Electron transfer in hydrogen-bonded systems represents a new and unique area of research, arising from the disparate fields of electron transfer and noncovalent self-assembly. To date, synthetic model systems feature electron donors (D) and acceptors (A) juxtaposed by hydrogen bond interfaces ($-\text{[H]}-$); a schematic of the basic system architecture is shown in Figure 1. Photon absorption initiates the transfer of an electron which, in its journey from donor to acceptor, must negotiate the proton and its motion within the interface. Accordingly, supramolecular systems of the type depicted in Figure 1 provide an opportunity to disentangle the various physical phenomena that govern how protons influence the rates of electron transfer.

The interplay between proton and electron transfers has far-ranging implications in biology, chemistry, and physics. For instance, proton motion coupled to electron transfer is the basic mechanism of bioenergetic conversion. Oxidases and reductases have structures optimized to gather energy along charge-separating networks to drive proton translocation. The resultant proton gradient gives rise to a trans-membrane chemical potential that provides energy for the activation of small molecules and the synthesis of complex biomolecules [1–3]. At the other end of the scientific spectrum, the coupling between proton and electron lies at the heart of the quintessential issues in electrochemistry such as hydrogen ion discharge at a platinum electrode [4, 5]. Recently, efforts in supramolecular solid-state chemistry have been directed toward the rational design of coupled electron–proton transfer systems with novel electronic or photonic properties [6–9]. From a more fundamental standpoint, electron transfer in hydrogen-bonded systems steps beyond the outer-sphere reactions treated by Marcus theory. The making and breaking of chemical bonds, occurrences not originally considered in Marcus theory, typically attend electron transfer in many oxidation-reduction reactions [10–15]. The systems depicted in Figure 1 display reactions of this type, as the overall oxidation-reduction

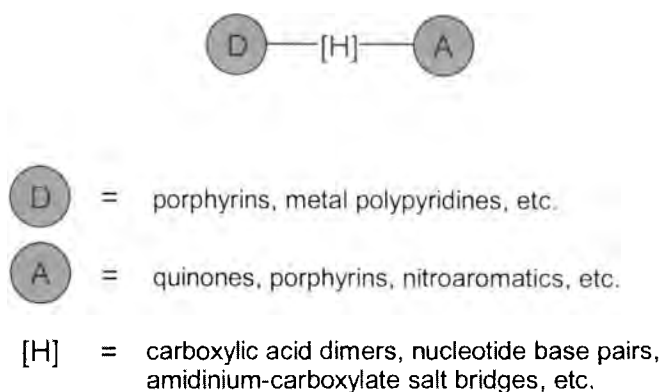

Figure 1. Schematic representation of hydrogen-bonded donor–acceptor supramolecules.

transformation may involve both electron transfer and bond-making/-breaking processes that accompany proton motion within the hydrogen bond interface.

4.2 Background

The hydrogen-bonded electron transfer construct depicted in Figure 1 finds its genesis in the original experimental systems by which electron transfer theory was validated. Through the 1970s, bimolecular electron transfers between donor (D) and acceptor (A) represented in Eq. 1, first in the form of self-exchange, and later as cross-reactions, created the basis for our understanding of electron transfer [16–18].

In these systems, the donor and acceptor diffuse together to give a precursor complex, $D\|A$, whose formation is described by the equilibrium constant K_p . Electron transfer, characterized by rate constant k_{ET} , occurs within the associated donor–acceptor pair, converting the precursor complex to successor complex $D^+\|A^-$. Subsequent separation of the oxidized donor (D^+) and reduced acceptor (A^-) from the successor complex is described by K_s . The rate of *intermolecular* electron transfer depends not only on the factors that influence k_{ET} but also on factors affecting the formation of the precursor complex [19]. More quantitatively, as described by Eq. 2, the expression for intermolecular electron transfer has the form of a consecutive reaction mechanism described by an observed rate constant (k_{obs}) consisting of rate constants for diffusion (k_d) and the activated electron transfer.

$$k_{obs} = \frac{k_{ET}k_d}{(k_{ET} + k_d)} \quad (2)$$

The diffusion limit will obscure very fast rates of electron transfer ($k_{\text{obs}} = k_{\text{d}}$ for $k_{\text{ET}} \gg k_{\text{d}}$) [16]. Even if electron transfer is slow with respect to diffusion ($k_{\text{obs}} = k_{\text{ET}}$), work accompanies the formation of the precursor complex and/or separation of the successor complex (this is especially prevalent when the reactants and/or products are charged). Work term contributions to the observed rate of reaction can overwhelm the intrinsic factors that govern the electron transfer event [19]. For this reason, excluding special circumstances [20–26], intermolecular reactions are not ideal systems for examining the mechanistic details of electron transfer.

Problems associated with precursor formation and successor dissociation are circumvented when the nonspecific interaction between donor and acceptor in Eq. 1, represented by \parallel , is replaced by a *covalent* linker. As the many chapters of this Series attest, the restriction of electron transfer to an *intramolecular* process, where the distance between donor and acceptor is fixed, has led, in the past two decades, to an explosion in our knowledge of electron transfer processes and the factors that control them. These include: the donor–acceptor separation distance; the nature of the intervening medium and the relative orientation between the donor and acceptor sites (all of which influence electronic coupling); the driving force of the reaction (ΔG°); and the nuclear reorganization of reactants and solvent (λ).

In the context of the foregoing discussion, the hydrogen-bonded donor–acceptor supramolecules of Figure 1 meld the constructs of both inter- and intramolecular electron transfer. From the standpoint of intermolecular electron transfer, these systems represent a preformed precursor complex held together by noncovalent interactions; from the standpoint of intramolecular electron transfer, these systems provide a fixed-distance donor–acceptor pair in which charge transport occurs along a noncovalent pathway.

The formation of the donor–acceptor complexes of Figure 1 occurs by “self-assembly”, which is defined as the noncovalent interaction of two or more molecular subunits to form an aggregate whose novel structure and properties are determined by the natures and positioning of the components [27–32]. The construction of complex, multicomponent aggregates requires intermolecular interactions that are directional and/or selective. The selectivity, particularly in asymmetric and multiply-bonded systems, allows for considerable influence over the association process by careful use of complementary components. With directionality, it is possible to control the separation and, in some cases, the relative orientation between donor–acceptor subunits.

Of the various noncovalent intermolecular interactions that have been exploited in supramolecule design, the hydrogen bond [29–31] has emerged as the paramount synthon for self-assembly. Following the definition put forth by Pimentel and McClellan in their classic 1960 text, *The Hydrogen Bond* [33], hydrogen bonds are noncovalent forces that arise when the proton of an acid is brought into intimate contact (i.e., a separation less than the sum of the van der Waals radii) with the nonbonding lone pair of a base. Despite this simple concept, a precise description of the electronic nature of the hydrogen bond continues to elude both theorists and experimentalists. This is due to the fact that hydrogen bonds form a more diverse range of interactions than do either covalent/ionic bonds or van der Waals forces; strong hydrogen bonds resemble the former and weak hydrogen bonds resemble the

latter. The reader is referred to Jeffrey's *An Introduction to Hydrogen Bonding* for structural and statistical studies on the strength and geometry of hydrogen bonds [34]. In the absence of unequivocal metrics for hydrogen bonding, Etter has used graph-set analysis based on X-ray diffraction data to propose a number of phenomenological rules for the assembly of complex aggregates arising from the formation of hydrogen bonds [35]. Although many additional factors outside the heuristics may influence the nature of the final superstructure, supramolecular chemists are now capable of exerting exquisite control of hydrogen-bonding networks towards the assembly of a variety of novel and structurally complex donor–acceptor systems. Against this backdrop of expertise, the D—[H]—A systems of Section 4.4 emerge.

4.3 Scope of the Chapter

In this chapter, we review electron transfer model systems where the hydrogen-bonded bridge provides a structural scaffold that is chemically and spatially unique from the donors and acceptors to which it is attached. The chapter is devoted to two basic classes of hydrogen bond networks: those that do not contain a permanent charge dipole (e.g., $-(\text{COOH})_2-$, guanine–cytosine, etc.) and those that do (e.g., amidinium–carboxylate). The first class of network is selective and directional, but the association strength varies greatly from case to case. The second class of network, succinctly denoted as a salt bridge, offers a combination of the selectivity and directionality of hydrogen bonds with the strength of a permanent electrostatic dipole. We focus on the particular salt bridge formed between amidinium and carboxylate, as this interface is of central importance to research efforts aimed at addressing the mechanistic details of the coupling between proton and electron. We designate the resulting dynamic process proton-coupled electron transfer (PCET).

Systems not covered in this chapter, but falling under the purview of non-covalently associated donor–acceptor pairs, include those in which the electrostatic scaffold directly comprises the donor and acceptor or in which the hydrogen bond interface is nonspecific. In the former case, the donor and acceptor carry opposite charges, and there is no unique scaffold providing the electrostatic interaction. Here, optical electron transfer is often observed in the form of an ion-pair charge transfer (IPCT). IPCT complexes were first identified by Linhard [36, 37] in the 1940s, and seminal work on such systems has since been carried out by Kochi [38–40], Billing [41, 42], Vogler [42, 43] and others [44]. This research has been extensively reviewed, most recently by Kochi in Volume II, Part 2, Chapter 2 of this handbook. Perhaps of more relevance to the present chapter, but not reviewed herein, are systems assembled from noncovalent electrostatic scaffolds that are unique from the donor–acceptor centers. These include “face-to-face” dimers and higher aggregates (represented schematically in Figure 2) formed by associated cationic and anionic macrocycles (e.g., porphyrins, phthalocyanines, porphyrazines) [45–63]. Photoinitiated electron transfer in these systems, which bear relevance to

Figure 2. Cofacial macrocycles associated via electrostatic interactions to give (a) dimers, (b) trimers and (c) higher aggregates. Typical cationic groups are pyridinium or trimethylanilinium; typical anionic groups are sulfonate or carboxylate. Boxes represent porphyrin, phthalocyanine or porphyrazine; $M = 2H, Zn, Cu, MnCl$, etc.

the special pair of the photosynthetic reaction center, has been monitored using transient absorption, emission and EPR techniques. An interesting application of electrostatically associated porphyrin systems for the activation of small molecules has been carried out by D'Souza and coworkers [64, 65]. Using self-assembled dimers of cationic and anionic cobalt porphyrins adsorbed on graphite electrodes, the efficient and selective catalytic four-electron reduction of oxygen to water is observed near physiological pH.

Lastly, biological or modified biological aggregates, such as protein-protein complexes [66, 67] and semi-synthetic cofactor assemblies [68], are not reviewed in the present chapter. Ill-defined electron transfer pathways as found in the one-point hydrogen bonding of simple organic solvent-solute interactions also will not be discussed. Mataga's noteworthy achievements in this latter area have been recently reviewed [69].

4.4 Electron Transfer Reactivity of $D-[H]-A$ Supramolecule Systems

Before discussing specific $D-[H]-A$ systems, it is appropriate to identify common experimental properties and modalities that are pertinent to their assembly and electron transfer reactivity. Because of the dynamic nature of noncovalent interactions, the supramolecular assemblies of this section have, for the most part, been characterized by spectroscopic techniques. Association constants for adduct for-

mation are usually determined using ^1H NMR, absorption or fluorescence spectroscopy. In extremely rare cases, assemblies have been characterized by X-ray crystallography; examples discussed later are a cofacial porphyrin–quinone complex, a protonated sapphyrin–benzoate adduct, and an amidinium porphyrin complexed with benzoate.

For virtually all of the supramolecular systems reviewed here, electron transfer is initiated by photoexciting the donor or acceptor; accordingly, either the donor or the acceptor must have a sufficiently long-lived excited state to support electron transfer. By using a photon to initiate the electron transfer event, a number of issues that may complicate the study of these self-assembled aggregates are readily resolved. For example, associated and unassociated donors and acceptors are present in solution owing to the equilibrium for the self-assembly of the hydrogen-bonded interface. For most systems, the pertinent excited-state lifetime is too short for diffusional electron transfer to come into play. Hence, photoinitiation of electron transfer from a donor to an acceptor selectively targets the associated pair, allowing one to view the intramolecular reaction in a “snapshot”. For systems with longer-lived excited states, concentration-dependent measurements allow intramolecular electron transfer through the hydrogen bond interface to be isolated from the non-specific bimolecular electron transfer reaction of unassociated and freely diffusing reactants. Another potential complication is the spontaneous mismatching of donor and acceptor subunits. Some interfaces are selective for donor–acceptor formation because they involve complementary interactions (e.g., Watson–Crick base pairs, amidinium–carboxylate salt bridges). For those interfaces that are not complementary, such as dicarboxylic acid scaffolds, donor–donor and acceptor–acceptor pairs will be present in addition to the desired donor–acceptor pair. However, formation of homodimers is inconsequential to the electron transfer kinetics because the charge separation reaction in homodimers is usually endothermic. Electron transfer will not be photoinitiated in these pairs.

We now present a selection of electron donor–acceptor supramolecules assembled via hydrogen bonding, organized according to the type of hydrogen bond interface employed.

4.4.1 Carboxylic Acid Dimers

The propensity of carboxylic acids to form cyclic dimers in low-polarity, non-hydrogen bonding solvents offers a facile, if not selective, method for assembling electron donor–acceptor pairs via a hydrogen-bonding interface. Indeed, the first systematic kinetics study of a hydrogen-bonded donor–acceptor pair employed a $-(\text{COOH})_2-$ motif in the construction of **1**, comprised of a carboxylic acid-modified zinc(II) porphyrin donor associated with a 3,4-dinitrobenzoic acid acceptor [70]. Assembly **1a** has an association constant of 552 M^{-1} in dichloromethane as determined by monitoring changes in the infrared CO and OH stretching vibrations. In good agreement with this result are association constants measured using static fluorescence quenching of the zinc(II) porphyrin excited state ($K_A = 698\text{ M}^{-1}$ for protio **1a** in *o*-dichlorobenzene and $K_A = 316\text{ M}^{-1}$ for deuterio **1b** in dichloromethane).

**1** (a, ^1H ; b, ^2H)

The zinc(II) porphyrin of **1** is particularly suitable for electron transfer studies because it is a photoactivated electron donor with easily monitored spectral properties. Forward and back electron transfer rate constants for **1a** ($k_F = 5.0 \times 10^{10} \text{ s}^{-1}$, $k_B = 1.0 \times 10^{10} \text{ s}^{-1}$) and **1b** ($k_F = 3.0 \times 10^{10} \text{ s}^{-1}$, $k_B = 6.2 \times 10^9 \text{ s}^{-1}$) were determined using picosecond transient absorption spectroscopy. Importantly, the static quenching of **1a** in CH_2Cl_2 is not observed when the carboxylic acid network is disrupted by the addition of hydrogen-bonding solvents or when the carboxylic acid functionalities of the donor–acceptor pair are esterified. Moreover, analysis of the transient absorption profiles of esterified control systems (where association of a donor–acceptor pair is obviated by esterification) provides no indication of porphyrin radical cation formation on the picosecond time scale.

System **1** is a benchmark in D—[H]—A electron-transfer studies because it provides the first direct experimental validation to the hypothesis that donor–acceptor coupling is affected by the presence and nature of the noncovalent interaction. Comparison of **1** with Wasielewski's covalently linked model system **2** [71], which

**2**

possesses a comparable donor–acceptor separation and driving force, reveals that the rates of electron transfer for these systems are of a similar order of magnitude. These results confirmed previous theoretical predictions [72–74] that hydrogen bond pathways for electron transfer can be competitive with covalent bond routes. More notably, the charge separation and recombination rate constants for **1** exhibit pronounced deuterium isotope effects ($k_{\text{H}}/k_{\text{D}} = 1.7$ and 1.6, respectively). As theoretically elaborated [75], it is this observed deuterium isotope effect that reveals coupling between electron and proton. Since charge redistribution within this interface is negligible, the only mechanism available to couple electron and proton arises from the dependence of electronic coupling on the position of the protons within the interface.

Following this same approach, Therien and coworkers studied model **3** [76]. This assembly represents an advance in the construction of D—[(COOH)₂—A systems inasmuch as the hydrogen bond scaffold is rigid. In an attempt to quantify the coupling between a donor–acceptor pair through a hydrogen bond interface, the electron transfer kinetics of **3** were compared to those of similar donor–acceptor pairs linked by interfaces composed of covalent carbon σ (**4**) and π (**5**) networks featuring the same number of bonds as **3**. However, an intervening phenyl ring may electronically isolate the hydrogen bond interface from the porphyrin excited state [77, 78]. Such electronic insulation of the electron transfer donor–acceptor centers from the interface will obviate coupling between the electron and proton. This is born out by the forward electron transfer rate constants of **3–5** (**3**, $k_{\text{ET}} = 8.1 \times 10^9 \text{ s}^{-1}$; **4**, $k_{\text{ET}} = 4.3 \times 10^9 \text{ s}^{-1}$; **5**, $k_{\text{ET}} = 8.8 \times 10^9 \text{ s}^{-1}$), which were measured by using time-resolved fluorescence spectroscopy to monitor the disappearance of the zinc(II) porphyrin singlet excited state in the presence of acceptor. The electron transfer rate constant is doubled when the donor–acceptor pair is bridged by the dicarboxylic acid interface **3** instead of the saturated bicyclic carbon bridge **4**; this result was attributed to greater electronic coupling mediated by the former type of scaffold. However, the conclusion is clouded by assumptions made in the determination of

redox potentials, which were deduced from porphyrin precursors rather than the electron transfer reactants themselves. The possibility of energy transfer, which is typically significant for donor–acceptor systems composed of zinc(II)–iron(III) porphyrin pairs [77, 79–82], was also not considered. Indeed, *ab initio* analysis of **3**–**5** [83] predicts that the hydrogen-bonded pathway of **3** exhibits weaker electronic coupling than the covalent bond pathways of **4** and **5**. This calculation is consistent with experimental results obtained for **1**, numerous other experimental systems (*vide infra*) and theoretical treatments of electron transfer along hydrogen-bonded pathways [72–74, 84].

4.4.2 Cofacial Porphyrin–Quinone Systems

The organization of porphyrins and quinones in a cofacial manner offers the opportunity to probe the effect of geometric factors on the electron transfer chemistry of this biologically important cofactor pair. When combined with hydrogen bond molecular recognition, a powerful, modular approach for examining a systematic series of molecular adducts is obtained. The cofacial presentation of quinones to porphyrins via hydrogen-bonding interactions is facilitated by the planarity of the porphyrin macrocycle and the ability to readily functionalize it to afford a shape-selective cleft for guest recognition. In addition, the aromaticity of the porphyrin ring provides a stabilizing force for guest quinones via π – π stacking and/or charge-transfer interactions.

Ogoshi, Aoyama and coworkers have exploited these properties of the porphyrin architecture to cofacially associate *cis*-bis(2-hydroxy-1-naphthyl) porphyrin **6** with a variety of *para*-quinones via two-point hydrogen-bonding and charge-transfer

6

interactions [85]. Association constants for these face-to-face host–guest adducts, measured using ^1H NMR and IR spectroscopy, range from $K_A = 7.8 \text{ M}^{-1}$ for tetramethoxy-1,4-benzoquinone to $K_A = 2.3 \times 10^2 \text{ M}^{-1}$ for anthraquinone. It was suggested that steric inhibition arising from the methoxy substituents is the reason for the lower binding affinity of the guest; however, it is not clear if the strength of hydrogen bonding and/or magnitude of π -stacking interactions can also play a role in stabilizing the porphyrin–quinone aggregates. The porphyrin–quinone complexes are completely nonfluorescent, consistent with an efficient intramolecular electron transfer from the photoexcited porphyrin to the bound quinone. Control experiments with a bis(naphthyl) porphyrin, possessing no recognition site, and *p*-benzoquinone show electron transfer to proceed only by a diffusion-limited quenching mechanism. Similar hosts for the recognition of *para*-quinones comprised of *cis*-bisamide-functionalized porphyrins **7–12** have been recently reported [86]. Studies of the binding of *p*-benzoquinone with **9** and **11** show that host–guest association of the bisamide clefts of **7–12** and the hydroxy-naphthyl cleft of **6** are comparable.

Ogoshi, Hayashi, and coworkers have elaborated their approach further by focusing on the recognition of ubiquinone (coenzyme Q_{10}) and its analogues. An important electron and proton carrier in the mitochondrial respiratory chain, ubiquinone contains a long isoprenoid tail and is able to move freely through the lipid bilayer to deliver electron/proton equivalents to oxidoreductases [87, 88]. Consequently, the noncovalent molecular recognition of ubiquinone at redox reaction receptor sites may regulate the rate of electron/proton transfer in the respiratory chain. Dynamic molecular recognition of the ubiquinone analog tetramethoxy-*p*-benzoquinone is achieved by *meso*-tetrakis(2-hydroxy-4-nonylphenyl)-porphyrin

7: $\text{R} = \text{C}_7\text{F}_{15}$

8: $\text{R} = \text{C}_7\text{H}_{15}$

9: $\text{R} = \text{CF}_3$

10: $\text{R} = \text{CH}_3$

11: $\text{R} = \text{C}_6\text{F}_5$

12: $\text{R} = \text{C}_6\text{H}_5$

**13**

13 [89]. As depicted in Figure 3, the guest acts as a trigger for the atropisomerization of **13** to enrich the particular $\alpha,\alpha,\alpha,\alpha$ -isomer by the induced interaction. The fluxional nature of the host–guest assembly can be thought of as a first step toward modeling the intricate structural docking interactions necessary for function in many biological systems.

Porphyrins **14** and **15**, containing four convergent hydroxy groups, form molecular clefts that bind tetramethoxy-*p*-benzoquinone to give 1:1 adducts [68, 90–94]. Association constants of the quinone guest with **14** and **15**, determined from absorption and fluorescence titration experiments, are $K_A = 7.9 \times 10^2 \text{ M}^{-1}$ and

Figure 3. Induced atropisomerization of **13** by quinone guest to enrich the particular $\alpha,\alpha,\alpha,\alpha$ -isomer.

**14****15**

$6.1 \times 10^5 \text{ M}^{-1}$, respectively. The single crystal X-ray structure of **14**-tetramethoxy-*p*-benzoquinone has been obtained (Figure 4). The separation distance of 3.35 \AA between the bound quinone and porphyrin agrees well with the van der Waals distance between aromatic rings (3.4 \AA). The four OH groups of the porphyrin host form the expected hydrogen bonds with the two carbonyl and four methoxy oxygens of the tetramethoxy-*p*-benzoquinone guest. Stern–Volmer plots indicate efficient fluorescence quenching of **14** and **15** in the low concentration range of quinone ($< 5 \times 10^{-3} \text{ M}$); in contrast, no fluorescence quenching of zinc(II) meso- $\alpha,\alpha,\alpha,\alpha$ -tetra(2-methoxy-1-naphthyl)porphyrin is detected in the same concentration range of quinone. Upon excitation at $\lambda = 570 \text{ nm}$, transient difference spectra of the **14**- and **15**-quinone adducts show a significant time-dependent absorption at 640 nm , which is characteristic of a zinc porphyrin cation radical. Estimates of the forward electron transfer rate constants are $k_{\text{ET}} \geq 4 \times 10^{11} \text{ s}^{-1}$ for both systems. Charge recombination rates for the quinone complexes of **14** and **15** are $k_{\text{ET}} = (1.1 \pm 0.4) \times 10^{11} \text{ s}^{-1}$ and $(6.8 \pm 0.3) \times 10^{11} \text{ s}^{-1}$, respectively. Both charge separation and recombination rate constants in these assemblies are comparable to those reported in covalently linked porphyrin–quinone systems.

D'Souza has studied assemblies of type **16** [95], which take advantage of the two-point hydrogen bonds formed by hydroquinone–quinone pairing to afford the quinhydrone acceptor. Lifetime measurements using single photon counting point

Figure 4. Thermal ellipsoid representation of **14**-tetramethoxy-*p*-benzoquinone. (Reprinted with permission from the American Chemical Society.)

16

toward enhanced electron transfer quenching of the electronically excited zinc(II) porphyrin by association of the second quinone. A comparison of these results with the measured reduction potentials indicates that the efficiency of fluorescence quenching scales logically with the oxidizing abilities of quinone and quinhydrone.

4.4.3 Quinone Recognition by Cyclophanes

In the systems of the previous section, direct recognition of the quinone by the porphyrin donor affords the noncovalent assembly. An alternative method for the construction of noncovalent assemblies is to append the porphyrin with remote cyclophanes that have the ability to recognize quinone acceptors via hydrogen bonding. Weedon and coworkers studied the EPR spectra of broad-band irradiated ($\lambda = 500$ nm) frozen solutions of β -cyclodextrin functionalized porphyrin **17** in the presence of various *p*-benzoquinones [96, 97]. Electron transfer was inferred from EPR signals assigned to the porphyrin cation and quinone anion radicals. Comparison of **17** with analogous bimolecular control systems points toward binding of the quinone in the hydrophobic pocket of the cyclodextrin to afford an efficient intramolecular electron transfer pathway.

The cyclodextrin-sandwiched porphyrin **18** of Kuroda [98] effectively recognizes hydrophobic quinones in water, with association constants ranging from $K_A = 7.4 \times 10^3 \text{ M}^{-1}$ for 1,4-naphthoquinone to $K_A > 5 \times 10^5 \text{ M}^{-1}$ for an adamantyl-functionalized benzoquinone. In contrast, the association of *p*-benzoquinone is negligible. Molecular modeling predicts that the quinone approaches the porphyrin from an out-of-plane direction. Time-resolved fluorescence measurements give an estimate of the intramolecular electron transfer rate constant on the order of 10^9 s^{-1} for all quinones studied.

Calixarenes have also been used as cyclophane hosts for the binding of quinone acceptors via hydrogen bonding. Arimura and Sessler have appended bis-hydroxy-containing calix[4]arenes to zinc(II) porphyrins. Two phenolic OH groups on the calix[4]arene serve as tweezers to complex a quinone via two-point hydrogen

17

18

19

bonding. The symmetric assembly **19** consists of a zinc(II) porphyrin containing two calix[4]arene functional groups [99]. Weiss and coworkers have reported a similar system for the multisite binding of transition metals, alkali or alkaline-earth metals and organic fragments [100]. Surprisingly, a Job's plot of the bis-functionalized porphyrin **19** with *p*-benzoquinone establishes the formation of the 1:1 host:guest complex, instead of the expected 2:1 adduct. A binding constant of $K_A = 40 \pm 10 \text{ M}^{-1}$, determined from ^1H NMR measurements, is considerably less than that observed for typical hydrogen-bonded complexes. This weak association of quinone to **19** may result from strong intramolecular hydrogen-bonding interactions between two adjacent hydroxy groups present in the calix[4]arene. Time-resolved fluorescence studies of the porphyrin in the presence of varying amounts of *p*-benzoquinone give a fluorescence decay profile with two components. A concentration-independent decay component is attributed to a quenching process involving unidirectional electron transfer from the calix[4]arene-Zn(II) porphyrin to bound *p*-benzoquinone. The photoinduced electron transfer rate constant is $k_{\text{ET}} = (8.0 \pm 0.2) \times 10^8 \text{ s}^{-1}$, with a quantum yield of $\Phi = 0.56$. The authors state that it is not clear whether electron transfer occurs through bond, solvent or both pathways. Ensemble **20**, containing a zinc(II) porphyrin with a calix[4]arene directly attached to one of the *meso* positions of the porphyrin ring, forms a 1:1 adduct with *p*-benzoquinone [101]. As for **19**, the formation constant for **20** is small ($K_A = 70 \pm 10 \text{ M}^{-1}$) and time-resolved

20

fluorescence measurements exhibit a fast (30-ps), concentration-independent decay component.

Amide-containing macrocycles have been examined by Hunter and coworkers as hosts for the recognition of a range of structurally related dicarbonyl compounds in nonpolar media [102, 103]. The dicarbonyl compounds are held in this type of receptor by a combination of two-point hydrogen bonding to the amide protons and π -stacking with the phenyl rings of the cyclic framework ($K_A > 10^3 \text{ M}^{-1}$). A pyridine-functionalized scaffold, equipped with convergent and divergent recognition sites, binds two cofactors, a zinc(II) porphyrin and *p*-benzoquinone, to form the termolecular electron donor–acceptor assembly **21**. The ternary complex is the predominant species (65 %) in a 1:1:1 mixture of the porphyrin, macrocycle and quinone at a concentration of $5 \times 10^{-3} \text{ M}$. The presence of the macrocycle greatly enhances the steady-state quenching of the porphyrin fluorescence by quinone. Control experiments show only a small decrease in porphyrin fluorescence on addition of quinone in the absence of macrocycle, attesting to intramolecular electron transfer within the 1:1:1 complex of **21**.

21

4.4.4 Peptide-Based Motifs

The search for protein or peptide-based “pathways” for electron transfer is an area of intense research. The most common secondary structures of proteins are the α -helix and β -sheet, with the latter most frequently employed in the construction of D—[H]—A systems. β -sheets consist of a two-dimensional array of fully extended polypeptide chains (β -strands) stabilized by a pattern of interchain hydrogen bonds. It has been suggested that the hydrogen bonding in β -sheets provides an efficient medium for long-range electronic coupling [104]. In order to assess the conduction efficiency of an electron through a β -sheet motif, a number of peptide-containing conjugates have been prepared.

**22**

Maruyama and Tamiaki have synthesized the elegant peptide-bridged porphyrin–quinone conjugate **22**, which mimics the β -turn structure found in proteins by forming a hydrogen-bonded loop [105]. Two eight-bond pathways are available for electron transfer: a through-backbone pathway and a through-hydrogen bond pathway. Photoexcitation of the free-base or zinc(II) porphyrin in **22** initiates electron transfer to the quinone acceptor. Electron transfer rate constants, determined from time-resolved fluorescence quenching measurements, are $k_{\text{ET}} = 2.1 \times 10^8 \text{ s}^{-1}$ and $4.0 \times 10^9 \text{ s}^{-1}$ for free-base-**22** and zinc(II)-**22**, respectively. These data suggest that electron transfer through the hydrogen bond pathway is slightly attenuated with respect to the corresponding covalent pathway.

Bowler and Williamson developed a similar donor–acceptor compound, **23**, with a β -turn-forming depsipeptide bridge [106], to study hydrogen-bond-mediated electron transfer through a single amide NH to CO bond. The placement of donor and acceptor is chosen to favor electron transfer through the hydrogen-bond interface of the β -turn. An advantage of **23** over **22** is the replacement of the central amide linkage with an ester, which ensures β -turn folding (eliminating the possibility of γ -turn folding). Infrared spectroscopy indicates that the β -turn conformation in **23** is approximately 85 % populated in nonpolar solvents such as CH_2Cl_2 , and completely disrupted in polar solvents like DMSO. Using time-resolved fluorescence spectroscopy, very fast electron transfer ($k_{\text{ET}} = 1.1 \times 10^9 \text{ s}^{-1}$) is observed in the presence of the β -turn. When the β -turn is disrupted (using DMSO), electron transfer is no longer competitive with the intrinsic fluorescence emission of the

23

porphyrin donor, indicating that the β -turn is an efficient coupling medium for electron transfer.

Ogawa and coworkers have examined peptide β -strand mimics of the general type **24** ($R = \text{CH}(\text{CH}_3)_2$, $n = 1-3$), consisting of a ruthenium(II) polypyridyl electron donor tethered to a cobalt(III) pentammine electron acceptor by an polyvaline peptide chain [107]. A related parallel β -sheet mimic has also been studied [108]. These compounds adopt the conformational properties found within the individual strands of a β -pleated sheet in both aqueous and methanol solutions. Emission lifetime measurements and HPLC product analyses suggest that the binuclear donor–acceptor compounds undergo photoinduced electron transfer. The values of k_{ET} decrease with increasing donor–acceptor distance according to $\beta = 1.1 \text{ \AA}^{-1}$, which is observed for electron transfers both in water at 298 K and in ethanol–

24

methanol glasses at 77 K. Notably, this value falls within the range for electron transfers occurring along the β -strands of ruthenium-modified azurin [109], and concurs with Gray and coworkers' [104] predictions for the rate of electron transfer along an individual strand of a β -sheet.

4.4.5 Watson–Crick Base-Pairing

The Watson–Crick base-pairing of DNA is perhaps the most ubiquitous example of how hydrogen bonding can shape and stabilize large, organized supramolecular assemblies. Sessler and coworkers have extensively exploited the two-point hydrogen bonding between adenine and thymine bases and the three-point hydrogen bonding between guanine and cytosine bases to construct a series of well-defined aggregates to study photoinduced electron transfer. Although **25** (R, R' = porphyrin, alkyl ether) was not designed for electron transfer investigations, ^1H NMR studies confirm the association of donor–acceptor pairs via guanine–cytosine subunits in non-polar solvents such as chloroform. Photophysical studies of this ensemble show efficient singlet and triplet energy transfer over 10 to 30 Å from the zinc(II) porphyrin donor to the free-base porphyrin acceptor [110, 111]. Control experiments verify that hydrogen bonding is essential for the observed photoprocesses. Fluorescence experiments using analogous donors and acceptors that lack the appended recognition units show no evidence of energy transfer at similar concentrations. Furthermore, the fluorescence of the photo-donor can be restored by the addition of ethanol, which causes a disruption of the hydrogen-bonding scaffold.

25

This same general approach can be used to promote electron transfer. Compound **26** poises a guanine-functionalized zinc(II) porphyrin donor at ~ 20 Å from a 2-cytosine-*p*-benzoquinone acceptor [112]. The aggregate, however, is quite flexible with many possible conformations. Analysis of the biphasic fluorescence decay curves of the guanine–zinc(II) porphyrin in the presence of its cytosine–quinone conjugate yields an electron–transfer rate constant of $k_{\text{ET}} = 4.2 \times 10^8 \text{ s}^{-1}$. Again, hydrogen bonding is necessary for function, as analogues without the appended nucleobases show no evidence of electron transfer at concentrations similar to those used for kinetics studies of **26**.

Due to concerns of through-space and through-solvent pathway contributions to the electron-transfer kinetics of **26**, a more rigid system, **27** (R = SiMe₂^tBu)

**26****27**

[113], was developed to better define the electron transfer reactivity of this class of ensembles. The association constant for **27**, derived from ^1H NMR titration measurements ($K_A = 1.6 \times 10^4 \text{ M}^{-1}$), is significantly higher than that observed for the flexible aggregate, thus pointing to the superior pre-organization of **27**. Time-resolved fluorescence measurements of **27** under conditions identical to those used to study **26** reveal that electron transfer in the former is notably faster ($k_{\text{ET}} \sim 8 \times 10^8 \text{ s}^{-1}$ for **27**) despite substantially less driving force ($\Delta G^\circ \sim -43 \text{ kJ mol}^{-1}$ for **27**, $\Delta G^\circ \sim -96 \text{ kJ mol}^{-1}$ for **26**). Related supramolecules **28** and **29** ($\text{R} = \text{SiMe}_2^t\text{Bu}$) have been prepared and their photoinduced energy-transfer processes have been studied [114]. Here, the rigid Watson–Crick hydrogen-bonding

30

motif allows for the association of either one or two guanosine-functionalized zinc(II) porphyrins with a mono- or dicytidine-free base porphyrin. The energy transfers occur with high quantum efficiencies ($\Phi = 0.62$ for the singlet–singlet transfer, $\Phi = 0.93$ for the triplet–triplet transfer).

The flexible porphyrin–anthracene system of Sirish and Maiya assembles via complementary adenine–thymine base pairing [115]. Ensemble **30** associates with a binding constant of $K_A = 47 \pm 5 \text{ M}^{-1}$. ^1H NMR data suggest that both Hoogsteen and Watson–Crick adenine–thymine associations exist in solution. Time-resolved fluorescence data are consistent with the possibility of energy and electron transfer from the singlet excited state of the anthracene to the porphyrin.

In order to determine more precisely and directly the parentage of the excited state donor in D(porphyrin)—[H]—A systems, Sessler, Levanon, and coworkers have undertaken time-resolved EPR spectroscopy of base-paired systems **27** and **31** ($\text{R} = \text{SiMe}_2^t\text{Bu}$) embedded in nematic liquid crystals [116, 117]. Selective pulsed laser excitation of the zinc(II) porphyrin at $\lambda = 532 \text{ nm}$ results in long-range electron transfer to the quinone or dinitrobenzene acceptor. Recently, a set of W-band time-resolved EPR experiments on **31** was carried out to observe directly the radical pair [118]. Electron transfer appears to originate from the triplet excited state of the porphyrin. This result has important ramifications for future investigations, because it challenges the assumption that electron transfer in D(porphyrin)—[H]—A systems occurs from the singlet excited state, which is too short-lived to support bimolecular reactivity. Conversely, electron transfer from porphyrin triplet excited states should encompass both intra- and intermolecular reaction kinetics. The results

31

of these studies therefore highlight the importance of determining the concentration dependence of electron transfer kinetics for all D(porphyrin)—[H]—A systems.

Electron transfer from long-lived triplet excited states is the rule rather than the exception when metal polypyridyl complexes, and not porphyrins, are the photoexcitable donors or acceptors. Constable and Fallahpour have described the preparation and recognition properties of a thymine-functionalized terpyridine and its bis-homoleptic iron(II) and ruthenium(II) complexes [119]. The ruthenium(II) complex forms specific two-point hydrogen bonds with an organic-soluble adenosine analogue. ^1H NMR studies of adduct **32** in CD_3CN over a temperature range of 248–298 K give the thermodynamic quantities $\Delta H = -1.60 \text{ kJ mol}^{-1}$ and $\Delta S = 22.33 \text{ J mol}^{-1} \text{ K}^{-1}$ with an extracted stability constant of $\log K_A = 1.44$ at 298 K.

Ward and coworkers have synthesized complexes **33–36** ($\text{R} = {}^t\text{Bu}$, $\text{M} = \text{Ru, Os}$), in which luminescent ruthenium(II) or osmium(II) tris-bipyridyl cores are functionalized with adenine, thymine, guanine, and cytosine, respectively [120, 121]. Mixing components **33** and **34** results in 1:1 adduct formation but with a rather small stability constant ($K_A \sim 100 \text{ M}^{-1}$); thus, the photophysical properties of the associated pair are difficult to study in the presence of large excesses of the free component parts. However, use of **35** and **36**, with the guanine–cytosine three-point hydrogen bond replacing the weaker adenine–thymine two-point hydrogen bond, circumvents this issue [122]. The association constant for ruthenium-**35** and osmium-**36** is $K_A \sim 6000 \text{ M}^{-1}$ in CH_2Cl_2 , and efficient quenching of the ruthenium energy donor by the osmium acceptor is observed. Along similar lines, Sessler and coworkers have prepared complex **37** ($\text{R} = \text{SiMe}_2{}^t\text{Bu}$) for possible hydrogen-bonding attachment to porphyrin chromophores [123].

32

Lastly, electron transfer in $D-[H]-A$ assemblies is not a prerogative of the excited states of metal complexes. Organic ensembles **38** and **39** ($R = \text{SiMe}_2^t\text{Bu}$), containing a dimethylaniline–anthracene redox pair, have been synthesized recently [124]. Preliminary time-resolved and steady-state fluorescence experiments indicate the occurrence of photoinduced electron transfer. In work related to Watson–Crick base-paired systems, the excited state of the fluorescent pyrene derivative **40** is efficiently quenched (94–99 %) by 2'-deoxyguanosine (dG), 2'-deoxycytidine (dC), or 2'-deoxythymidine (dT) in aqueous solution [125]. A PCET mechanism is thought to be responsible for this process, as the thermodynamics of electron transfer are unfavorable unless coupled to a rapid proton-transfer step. The quenched lifetime of **40** in the presence of dC and dT in H_2O is significantly extended by a factor of 1.5–2.0 in D_2O ; this isotope effect is similar to that observed in the kinetics studies of **1** [70]. The invoked PCET reaction mechanism also accounts for the inability of dC and dT to quench the fluorescence of **40** in the aprotic organic solvent DMSO.

4.4.6 Diimide-Based Assemblies

Diimide functionalities provide an attractive hydrogen-bonding scaffold for the association of donor–acceptor pairs. In all the examples surveyed here, the electron acceptors are derivatized naphthalene- or benzene-tetracarboxamides; these acceptors have proved particularly useful for analysis of electron transfer reactions owing to the characteristic absorptions of their anion radicals. Osuka, Okada,

36

35

34

33

37

38

39

**40****41**

Mataga and coworkers have synthesized a zinc(II) porphyrin functionalized with a 2,6-diacylaminopyridine moiety; this porphyrin recognizes a siloxyl-modified naphthalene-tetracarboxamide through a three-point hydrogen-bonding interaction to form donor–acceptor adduct **41** ($R = \text{SiMe}_2^t\text{Bu}$) [126]. The benzene-tetracarboxamide analogue has also been prepared. The high association between naphthalene-tetracarboxamide and porphyrin to produce **41** ($K_A = 1.6 \times 10^4$ and $1.3 \times 10^5 \text{ M}^{-1}$ in CDCl_3 and C_6D_6 , respectively) is attributed to a geometrically matched interaction, as the benzene-tetracarboxamide analogue, which contains a five-membered cyclic diimide ring, binds much less tightly ($K_A = 2.9 \times 10^2 \text{ M}^{-1}$ in C_6D_6). The efficient quenching of porphyrin fluorescence by the naphthalene-tetracarboxamide in C_6D_6 is inhibited in polar solvents such as THF, which suppresses the association of the donor–acceptor pair. Absorption bands corresponding to the reduced tetracarboxamide acceptor decay within 20 ps of photoexciting benzene solutions of **41**, suggesting that charge separation and recombination are very rapid.

More tractable electron transfer kinetics are observed for assembly **42** ($R = \text{SiMe}_2^t\text{Bu}$), which consists of a donor–acceptor pair similar to that of **41** but oriented in a side-on manner [127]. The association constants for the matched three-

**42**

point hydrogen bonding in this system are $K_A = 280$, 100, and 79 M^{-1} in benzene, CDCl_3 , and CD_2Cl_2 , respectively. A Job's plot is consistent with a 1:1 complexation stoichiometry. As **41**, efficient quenching of the porphyrin excited state pair is not observed in polar solvents such as THF or DMF, indicating that complexation via hydrogen bonding is crucial for efficient fluorescence quenching. Upon photoexcitation of supramolecule **42** at $\lambda = 532 \text{ nm}$ in benzene, the time-resolved transient absorption spectrum shows the unequivocal formation of a charge-separated state. Formation of both the diimide anion (474 nm) and zinc porphyrin cation (655 nm) radicals were observed at 20 ps; each radical subsequently decayed with a time constant of 270 ps, giving a rate constant for charge recombination of $k_{\text{ET}} = 3.7 \times 10^9 \text{ s}^{-1}$. Time profile analysis of the absorption band maximum (458 nm) of the S_1 state of the zinc porphyrin yields a rate constant for charge separation of $k_{\text{ET}} = 4.1 \times 10^{10} \text{ s}^{-1}$. A pronounced deuterium isotope effect for **42** is found for both charge separation ($k_{\text{H}}/k_{\text{D}} = 1.4$) and recombination ($k_{\text{H}}/k_{\text{D}} = 1.5$), similar to what was observed for the electron transfer kinetics of **1** [70]. For comparison, transient absorption studies of covalently linked model **43**, with similar

**43**

44

driving force and a slightly shorter estimated center-to-center distance (14.7 Å for **42**, 12.8 Å for **43**), give rates of $k_{\text{ET}} = 9.9 \times 10^{10} \text{ s}^{-1}$ and $6.7 \times 10^8 \text{ s}^{-1}$ for charge separation and recombination, respectively. Taken together, the results from kinetics studies of **42** and **43** provide additional experimental support to the notion that hydrogen bonds can provide an efficient bridge for mediating electron transfer.

A naphthalene-tetracarboxamide acceptor has also been employed by Sessler and coworkers in the rigid framework of **44** (Ar = 3,5-(^tBu)₂-phenyl, R = ^tBu) which features a chlorin as the singlet-excited state electron donor [128]. A three-point hydrogen bond stabilizes a coplanar supramolecular complex with a ~ 7 Å edge-to-edge distance between the redox sites. Association constants for the assembly are $K_{\text{A}} = 663 \text{ M}^{-1}$ and 364 M^{-1} in toluene and CDCl₃, respectively. Steady-state fluorescence and single-photon counting studies of **44** suggest electron transfer. However, the picosecond transient absorption spectrum shows no evidence for the formation of the diimide anion radical upon irradiation of **44** at $\lambda = 532 \text{ nm}$. In light of these results, Sessler and coworkers propose that the rate of charge recombination is greater than the rate of charge separation to such an extent that the concentration of the ion-pair species cannot build to an observable level.

4.4.7 Mixed-Valence Metal Complexes

Within the Hush formalism of electron transfer [129], the electronic coupling through hydrogen bond interfaces may be deduced from the intensity of a mixed-valence transition between juxtaposed donor–acceptor pairs. We highlight the only such detailed study in this section. Curtis and coworkers have studied a collection of hydrogen-bonded mixed-valence adducts formed between ruthenium(II) electron-donor and ruthenium(III) electron-acceptor complexes in solution [130]. Using acetonitrile or nitromethane as a solvent, hydrogen-bonded assemblies of the type $\{[(\text{tpy})(\text{bpy})\text{Ru}^{\text{II}}(\text{CN})_2]_2, (\text{en})_2\text{Ru}^{\text{III}}(\text{bpy})\}^{5+}$ **45** (bpy = 2,2'-bipyridine, tpy = 2',6'', 2'-terpyridine, en = ethylenediamine) and $\{[(\text{bpy})_2\text{Ru}^{\text{II}}(\text{CN})_2]_2, (\text{en})_2\text{Ru}^{\text{III}}(\text{bpy})\}^{3+}$

45

46

46 are produced. The 2:1 stoichiometry of the ternary aggregates is verified according to Job's method. The self-assembly of the systems is thought to proceed through hydrogen bond interactions between the protons of the en ligands (acid donors) and the nitrogens of the cyanide ligands (base acceptors). The electrochemical waves for the one-electron redox reactions of the individual metal centers separate when measurements are performed in low-donor solvents. The magnitude of this separation suggests that two hydrogen bonds are approximately twice as effective as one for establishing electronic communication between metal redox centers. Direct evaluation of the electronic coupling energies from absorption spectra [129] shows that electronic coupling through the hydrogen bonds of both the mono and dicyano adducts is approximately 65–75 % as efficient as through σ -covalent bonds of the known dithiaspiroalkane-bridged systems [131–133]. Compared to π -conjugated bridging pathways, the coupling through the hydrogen bonds of **45** and **46** is approximately 30–40 % as strong. These interesting results clearly merit further research in the area of mixed-valence metal complexes containing hydrogen bond bridges.

4.4.8 Barbituric Acid-Containing Complementary Pairs

Hamilton and coworkers have prepared well-organized assemblies of type **47** ($R =$ benzyloxycarbonyl), which associate in CH_2Cl_2 via six hydrogen bonds between a porphyrin–barbiturate conjugate and a bis(2,6-diaminopyridine)-derivatized receptor [134]. The estimated distance between the self-assembled centers is $\sim 23 \text{ \AA}$. Efficient energy transfer from a dansyl-functionalized receptor to the porphyrin–barbiturate guest is observed by emission quenching. Control experiments with a dansyl derivative incapable of hydrogen bonding show no fluorescence quenching. Knapp, Isied and coworkers have elaborated this general approach in the preparation of a series of ruthenium(II) tris-bipyridine complexes, **48–50** ($R = \text{'Bu}$), appended with barbituric acid or barbital groups [135, 136]. Complexes **48–50** associate with a multifunctionalized amidopyridine host **51** to form 1:1 adducts in chlorinated solvents. Significant binding ($K_A \sim 10^2 \text{ M}^{-1}$) is observed only for guest **49** in its enolate form, which is promoted over the keto form by the cationic ruthenium(II) center. Studies of electron transfer between osmium and ruthenium polypyridines bridged by this motif have recently been undertaken [137]. Comparison of the electron transfer rate constants observed to those obtained for analogous covalently bonded complexes [138] shows that charge transport is only modestly slower in the hydrogen-bonded systems.

4.4.9 Miscellaneous Hydrogen-Bonded Ensembles

A number of other hydrogen-bonded assemblies containing photoactive groups warrant mention here. Lehn and coworkers have described the self-assembly of a supramolecular cofacial bisporphyrin cage **52** ($R, R' =$ decyl, octyl) via 12 hydrogen bonds [139]. Unlike the porphyrin monomer, whose fluorescence is highly concentration-dependent due to self-quenching via π -stacking aggregation, the fluorescence intensity of bisporphyrin cage **52** is remarkably constant over the con-

**52**

centration range of 1 to 10 mM. When ethanol containing 0.1 % HCl is added to a dichloromethane solution of **52**, the emission reverts to that of the unassembled protonated porphyrin at that same concentration.

Sessler and coworkers have investigated the photophysical properties of systems based on anion chelation by monoprotonated sapphyrins. Archetypal ensemble **53**

[140, 141], consisting of a monocarboxyporphyrin and a protonated pentapyrrolic saphyrin, forms in CH_2Cl_2 with an association constant of $K_A \sim 10^3 \text{ M}^{-1}$. The proclivity of the saphyrin to bind carboxy guests was established using high-resolution FAB mass spectrometry; in the case of the benzoate adduct, an X-ray crystal structure was also obtained (Figure 5). Upon irradiation of **53** at $\lambda = 417 \text{ nm}$, singlet–singlet energy transfer from the porphyrin to the saphyrin occurs; spectral data are consistent with a Förster-type mechanism. Porphyrin dicarboxylates bind inside the cleft of an amide-linked cofacial saphyrin to form aggregates of the type represented by **54** [142]. Affinity constants are on the order of $K_A \sim 10^5 \text{ M}^{-1}$ in nonpolar solvents such as dichloromethane. Steady-state fluorescence

Figure 5. Thermal ellipsoid representation of the protonated saphyrin of **53** complexed with benzoate. (Reprinted with permission from the American Chemical Society.)

measurements support the conclusion that photoinduced energy transfer occurs between the porphyrin subunit and the sapphyrin dimer.

Gust, Moore, Moore and coworkers' covalent cartenoid–porphyrin–quinone molecular triads **55**–**60** contain a cyclized hydrogen bond within the quinone acceptor framework [143]. The naphthaquinone moiety of **55** is fused to a norbornene system whose bridgehead position bears a carboxylic acid, which can hydrogen bond to an adjacent quinone. Photoinduced electron transfer from the porphyrin to the quinone leads to a marked pK_a increase of the latter, resulting in a fast proton transfer ($k_{PT} \sim 10^{12} \text{ s}^{-1}$) to form the semiquinone. Back electron transfer from the semiquinone is attenuated as a consequence of the proton-stabilized charge-separated species. This leads to a two-fold increase in the quantum yield of the charge-separated state of **55**, as compared to those of the reference triads **56** and **57** (see Volume III, Part 2, Chapter 2).

Self-assembly of monopyrazolylporphyrins by hydrogen bonding has been examined by Ikeda and coworkers [144]. IR spectral measurements of the pyrazole NH stretches indicate that self-aggregates hydrogen bond at concentrations above $\sim 10^{-2} \text{ M}$. The identities of cyclic dimer **61** and tetramer **62** are confirmed by electrospray ionization mass spectrometry (ESI). ^1H NMR titrations in CDCl_3 give association constants of $K_A \sim 39 \text{ M}^{-1}$ and $\sim 9.3 \times 10^{-3} \text{ M}^{-1}$ for **61** and **62**, respectively. No electron transfer studies on these systems have yet been undertaken.

4.4.10 Salt Bridge Systems

In the D—[H]—A systems of Sections 4.4.1 to 4.4.9, little charge redistribution occurs within the interface upon electron transfer. For instance, in the symmetric dicarboxylic acid interfaces of Section 4.4.1, proton displacement from one side of

55: R₁ = Q₁; R₂ = Car

56: R₁ = Q₂; R₂ = Car; R₃ = Cl

57: R₁ = Q₂; R₂ = Car; R₃ = H

58: R₁ = Q₁; R₂ = H

59: R₁ = Q₂; R₂ = H; R₃ = Cl

60: R₁ = Q₂; R₂ = H; R₃ = H

62

the dicarboxylic acid interface is compensated by the concomitant displacement of a proton from the other side. Because charge redistribution within this interface is negligible, the effect of the proton on electron transfer kinetics is small. As noted in Section 4.4.1, the only mechanism available to couple proton and electron in this type of system arises from dependence of the electronic coupling on the position of the protons within the interface. As demonstrated by many systems presented in Section 4.4, coupling through a hydrogen bond interface is only slightly inferior to that through a covalent pathway. In both cases, electron transfer is fast. Similar results are obtained for donor-acceptor centers separated by base pairs [145], which cannot be ionized. These cases, however, are unusual in biology, where uncompensated proton displacement typically accompanies the redox process. The charge shift resulting from electron *and* proton motion couples to the polarization of the

surrounding environment [146–152], thus providing a unique mechanism for PCET [22, 148]. In this case, changes in polarity, charge and energetics resulting from electron transfer are affected by proton displacement within the interface. To explore the importance of these issues, we have begun exploring PCET reactions that are mediated by a salt bridge, which combines the dipole of an electrostatic ion-pair interaction with a hydrogen-bonding scaffold.

Our initial work is based on the amidinium-carboxylate salt bridge, with flanking electron donors and acceptors. This interaction models the arginine–aspartate (Arg–Asp) salt bridge, an important stabilizing structural element in many biological systems including the active sites of dihydrofolate reductase [153], cytochrome *c* oxidase [154–158] and siroheme reductase [159]. Unlike Arg–Asp, which has multiple guanidinium-carboxylate interactions, amidinium presents two N–H bonds to carboxylate in one specific binding mode, thereby simplifying PCET studies. The two-point hydrogen bond of the amidinium-carboxylate interface features two favorable secondary interactions [160, 161] supported by the electrostatic stabilization of proximal opposing charges within the salt bridge. Accordingly, the amidinium-carboxylate salt bridge readily forms and association persists in solution, even when the dielectric constant of the solvent is high. Counterions are not required to stabilize this interface since the salt bridge may be formed directly from free amidine and carboxylic acid.

Ruthenium polypyridyl systems

The effect of the salt bridge on electron transfer can be determined directly by a comparative kinetics study of a D–[amidinium-carboxylate]–A complex and its switched interface D–[carboxylate-amidinium]–A congener. We have reported such a study for a supramolecular series of complexes where the donor is a ruthenium(II) polypyridyl with one bipyridine (bpy) ligand modified by either amidinium or carboxylate and the acceptor is the complementarily modified 3,5-dinitrobenzene (DNB) [162, 163]. The same donor–acceptor pair bridged by a symmetrical dicarboxylic acid interface has also been examined.

The assembly of supramolecules **63–65** (R = H, Me) was characterized by ^1H NMR, and absorption and infrared spectroscopy. Job's plots confirm the 1:1 adduct formation between the modified-ruthenium polypyridyl and its appropriate 3,5-DNB partner. In low-polarity solvents, association constants for **63** and **64** are large (in CH_2Cl_2 , $K_A = 5.6 \times 10^5 \text{ M}^{-1}$ and $K_A > 10^7 \text{ M}^{-1}$, respectively). The smaller association of **63** is consistent with the electron-withdrawing nitro groups conferring a decreased basicity on the carboxylate group of the 3,5-DNB acceptor, thus resulting in a weaker hydrogen-bonding interaction.

Supramolecules **63–65** were designed to exploit the well-known redox chemistry of electronically excited $[\text{Ru}(\text{bpy})_3]^{2+}$ -type complexes with nitroaromatics [164]. For both systems (R = H and Me), the excited-state lifetime of the Ru(II) polypyridyl donor is sufficiently long that concentration-dependent and -independent kinetics were observed. The concentration-dependent rate arises from the bimolecular electron transfer reaction between uncomplexed Ru(II) polypyridyl donor and the 3,5-DNB acceptor. The measured bimolecular rate constants were in ac-

cordance with that measured by Meyer and coworkers for the reaction between $[\text{Ru}(\text{bpy})_3]^{2+}$ and dinitrobenzene [164]. Moreover, the rate constants were similar to those observed when the carboxylate was esterified, preventing association between the amidinium and nitro functionalities (confirmed by NMR). The concentration-

independent lifetime decay component was attributed to the intramolecular PCET rate process of **63–65**.

A reliable kinetics study of the electron transfer reactions of **63–65** demands that the excited-state structure of the ruthenium(II) polypyridyl complexes be properly designed. Electron transfer in these assemblies is initiated by laser excitation of the metal-to-ligand charge transfer (MLCT) transition of the ruthenium(II) polypyridyl complex. Depending on the energetics of the MLCT excited state, two potential reaction pathways arise for the oxidative quenching reaction. For the case where the lowest energy MLCT excited state is localized on the bpy ligand modified with the salt bridge, the excited electron will be placed directly on the PCET pathway. Conversely, a lowest-energy MLCT excited state involving the ancillary bpy ligand will send the excited electron away from the PCET reaction pathway. In the absence of methyl substitution of the bpy rings, the MLCT excited states involving the ancillary bpy and the amidinium- or carboxylate-modified bpy are close in energy, thereby obscuring a comparative PCET study [163]. By tetramethylating the ancillary bpy ligands (tmbpy), the resulting tmbpy MLCT excited state is energetically destabilized by approximately 0.4 eV with respect to the MLCT excited states of either the amidinium- or carboxylate-modified bpy. Accordingly, photoexcitation of **63–65** (R = Me) cleanly promotes the transferring electron onto the salt bridge-functionalized ligand, from where it can smoothly advance to the DNB acceptor.

As shown by the data in Table 1, the unimolecular electron transfer rate constant within the D—[carboxylate-amidinium]—A assembly **64** is a factor of ~ 100 faster than that for assembly **63**, in which the interface is oriented in the opposite direction. This rate disparity may have several origins. For **63**, the permanent dipole of the salt bridge is in the direction of electron transfer. In contrast, the electron transfer pathway in **64** opposes the salt bridge dipole. Internal electrostatic fields affect the rates of electron transfer by altering the driving force of reaction relative to the isolated constituents. This results in an unfavorable energetic contribution in the case of **63** and a favorable one in the case of **64**. The thermodynamics may be further modified by reorganization energies associated with the salt bridge. In **63**, a proton shift from the ruthenium(II) amidinium donor to the carboxylate acceptor can stabilize the developing charge of the electron on the acceptor. Since the proton charge is strongly coupled to the solvent dipoles, charge shift within the salt bridge will be accompanied by significant solvent polarization, thereby giving rise to ad-

ditional Franck–Condon factors. For D—[carboxylate-amidinium]—A, the proton already resides on the acceptor, and there it is likely to remain upon the arrival of the electron. Franck–Condon factors are thus minimized for **64**. It should be emphasized that complete proton transfer in **63** is not necessary for the PCET to be strongly perturbed; any shift of the proton from its initial state will affect the Franck–Condon factors for PCET [146–152]. Finally, differences in hydrogen bond strengths in these asymmetric interfaces may play a role in the efficiencies of electronic coupling. The electron-withdrawing nitro groups on the acceptor will stabilize the negative charge on the carboxylate, resulting in a weaker hydrogen bond for **63** than for **64** and, hence, a correspondingly weaker electronic-coupling pathway.

With the electronic framework established for the PCET reactions of ruthenium(II) polypyridyl complexes, we wondered whether the influence of the salt bridge on electron transfer rates was specific to an oxidative quenching pathway. Thus, we also investigated the electron transfer reactions of ruthenium(II) polypyridyls bound to electron donors. In the case of the reductive quenching pathway, the PCET reaction effectively amounts to hole transfer through the amidinium-carboxylate bridge. Accordingly, the excited electron must be removed from the PCET pathway upon MLCT excitation—an effect that is achieved by modifying the ancillary bpy ligands with electron-withdrawing diethylcarboxy groups. Assemblies **66** and **67** are formed by mixing the ruthenium(II) polypyridyl acceptor with its

appropriate amidinium or carboxylate-modified dimethylaniline (DMA) partner [165]. As determined by a Benesi–Hildebrand fit of the change in absorption of the ruthenium complex MLCT band as a function of added DMA derivative, association constants for **66** and **67** are $K_A = 2.8 \times 10^4 \text{ M}^{-1}$ and $5.5 \times 10^3 \text{ M}^{-1}$, respectively. A unimolecular electron transfer rate of $k_{\text{PCET}} = 1.7 \times 10^9 \text{ s}^{-1}$ is found for **66**, for which proton motion is minimized. As expected on the basis of the above PCET considerations, this behavior of the reductive quenching pathway is in contradistinction to the oxidative quenching results for **63** and **64**. Unfortunately, a more explicit analysis of the effect of the salt bridge on the electron transfer pathway is obviated by the large differences in driving force between **66** and **67**. Nonetheless, the overall electron transfer kinetics of **63–67** clearly show that PCET kinetics in salt bridge assemblies are dominated by the orientation of the salt bridge relative to the direction of electron transport. The fastest rates of electron transfer for both oxidative and reductive quenching pathways are observed when the electron is transferred to the site already carrying the positive charge of the interface.

Porphyrin supramolecules

The large changes in optical density for electron and proton transfer products of porphyrin-based systems make them ideal candidates for studying PCET by transient spectroscopy. We have adapted Garigipati's strategy [166] to prepare porphyrin amidines for the first time by reacting nitriles with Weinrub's amide transfer reagent [167], methylaluminum(III) chloramide. The complex of zinc(II) vinyl amidine porphyrin **68** with acceptor 3,4-DNB exhibits a unimolecular electron transfer rate constant of $k_{\text{PCET}} = 7.5 \times 10^8 \text{ s}^{-1}$ as determined by time-resolved fluorescence spectroscopy [168].

68

With the objective of introducing a more rigid linking scaffold than the one provided by **68**, an elaborate synthetic strategy has been developed to introduce amidinium functionalities directly onto the porphyrin ring at the β position; **69**, which is exemplary of our efforts, affords a detailed characterization of the PCET network [169]. Though the proclivity for salt bridge formation was firmly established previous to **69**, we had not characterized by X-ray structural analysis an electron donor–acceptor complex assembled by an amidinium–carboxylate interface. With its absence of counterions, the X-ray crystal structure shown in Figure 6 highlights the simplicity of **69** for PCET studies. NMR studies unequivocally show that the assembly is preserved in solution. The concentration-dependent downfield shift of

zinc(II)-69-3,5-DNB

Figure 6. Thermal ellipsoid representation of nickel(II)-69 complexed with benzoate.

amidinium protons involved in hydrogen bonding (NH_{ax} varying by >2 ppm) to the carboxylate is contrasted by an insensitivity of the chemical shift (<0.5 ppm) for the amidinium protons external to the salt bridge (NH_{eq}). Such behavior has emerged as a signature of salt bridge formation. Additionally, *meso* protons are a sensitive measure of π -stacking in porphyrin systems [170, 171]; in **69** they do not shift, indicating that π -stacking is not an important mechanism of association. This is also expected on the basis of thermodynamic considerations; π -stacking is a much weaker interaction than the two-point hydrogen bond of the salt bridge. Association constants of nickel(II)-**69** with the carboxylate are exceptionally large ($K_{\text{A}} = 7.7 \times 10^5 \text{ M}^{-1}$ in CH_2Cl_2), even when the dielectric constant of the solvent is high ($K_{\text{A}} = 280 \text{ M}^{-1}$ in DMSO).

The Soret and Q-bands of the porphyrin undergo a blue shift immediately upon association of zinc(II)-**69** to the carboxylate ion. The perturbation of the absorption profile upon salt bridge formation suggests that the interface is strongly coupled to the porphyrinic chromophore and correspondingly to the electron transfer pathway. Upon excitation of the salt bridge complex of zinc(II)-**69** and acceptor 3,5-DNB, photoinitiated electron transfer occurs; a unimolecular rate constant of $k_{\text{PCET}} = 6.4 \times 10^7 \text{ s}^{-1}$ is calculated from the fluorescence decay kinetics. The electron transfer rate constant for the associated salt bridge complex is considerably smaller than that of covalently linked zinc(II) porphyrin donor–acceptor systems. For example, an electron transfer rate constant of $k_{\text{ET}} = 3 \times 10^{10} \text{ s}^{-1}$ is found for Wasielewski's zinc(II) porphyrin–[Sp]–quinone (Sp = rigid polycyclic bridge) system **2** at equivalent driving forces ($\Delta G^\circ = -0.30 \text{ eV}$) [71]; this faster rate is even more striking considering the longer electron transfer distance in **2** (edge-to-edge distance: zinc(II) porphyrin–[Sp]–quinone = 10.5 \AA ; **69**-DNB = 7.0 \AA). Undoubtedly, the pronounced effect of the interface protons on the kinetics of **69**-DNB arises from their strong coupling to the electron transfer pathway, engendered by the direct attachment of the salt bridge network to the porphyrin donor macrocycle.

4.5 Concluding Remarks

With the field of hydrogen-bonded electron transfer in its infancy, new frontiers await exploration and numerous issues remain to be addressed. The D—[H]—A supramolecules of the preceding sections define two basic PCET reaction mechanisms:

- 1) Electron transfer occurs through a hydrogen bond interface in which the interface proton(s) is(are) effectively stationary; here, the hydrogen bond mediates the efficiency of electron conduction.
- 2) Proton motion within the interface accompanies the electron transfer event; hence, charge rearrangement results from the motion of both the electron *and* the proton.

Placing these two cases in context, simple electron transfer (ET) is generally defined within the Marcus–Levich framework,

$$k_{\text{ET}} = V_{\text{el}}^2 \cdot FC_{\text{ET}} \quad (3)$$

where V_{el} is the electronic coupling and FC_{ET} is the Franck–Condon weighted density of states. Electron transfers described by 1) and 2) step beyond this basic model because both the electron *and* the proton may affect V_{el} *and* FC (for this case we define a FC_{PCET}). V_{el} will depend parametrically on the position of the proton in the interface; extensive charge redistribution (e.g., salt bridge systems of Section 4.4.10) will lead to FC_{PCET} contributions. The FC_{PCET} effect is specific to case 2). To understand the origins of the FC_{PCET} factor, consider again a simple electron transfer reaction. The electron tunnels through the potential barrier from donor to acceptor when the solvent fluctuates to a configuration where the energies of the reactants and products are essentially equal. For case 2), the electron *and* proton tunnel and now both events are induced by solvent fluctuations; coupling arises because the electron and proton influence each other thermodynamically and kinetically [146–152]. As the electron moves, the $\text{p}K_{\text{a}}$ s of the donor and acceptor will change; but to predict kinetics, the driving force (ΔG°) of the reaction is not sufficient. The FC_{PCET} factors will also be affected by changes in ΔG° and by the charge redistribution resulting from electron *and* proton motion. Thus, any motion of the proton from its initial position will perturb V_{el} and FC_{ET} , thereby affecting the kinetics for electron transfer.

The many systems described in Section 4.4, as well as the D—[H]—A supramolecules that continue to emerge, provide ample opportunity to investigate and assess quantitatively the role of hydrogen bonding and protons on electronic coupling (i.e., the problem defined by 1)). It is already clear from the large body of work performed to date that electronic coupling through a hydrogen bond is smaller, but only slightly so, than that through a covalent bond. The richer problem defined by 2) is just beginning to be examined on an intimate mechanistic level, and there are a number of fundamental questions that warrant investigation. What is the timing between the electron and the proton, and what factors distinguish synchronous and asynchronous transfer of the electron and proton? What are the structural/electronic features of the PCET network by which the proton and electron communicate with each other? With the additional charge redistribution resulting from proton motion, how do the energetics (e.g., reorganization, free energy) of charge transfer in a PCET reaction differ from those in an ET reaction?

Answers to these questions are predicated on the ingenious design of new supramolecular systems. First and foremost, well-defined model systems that allow the independent timing of proton and electron are needed; some systems—notably those described in Section 4.4.10—are poised to attack this issue because they display unique spectroscopic signatures for the transfer of the electron and the proton. In addition to directly probing the sequence and rates of the two events, kinetic isotope effects for the proton and the electron transfers may be ascertained. Isotope effects have been used to infer PCET mechanisms in oxygen activation by model

compounds and enzyme catalysis. Meyer's measurements of the kinetic isotope effects of hydroxo to oxo conversion in ruthenium polypyridyl compounds [172–174], and Mayer's studies on hydrogen atom abstraction by various metal-oxo compounds [175] have led to the conclusion that such reaction mechanisms involve concerted PCET. Similarly, Klinman has pioneered the use of isotope effect measurements on a variety of enzyme processes involving proton/hydrogen atom/hydride transfers to construe mechanistic details of the PCET pathways in a variety of enzymatic transformations [176, 177]. In these biocatalysis and catalysis studies, the isotope effects are determined from substrate disappearance and/or product appearance kinetics, which can encompass a mechanistic complexity extending beyond PCET. As Klinman notes, the interpretation of results is highly dependent on theoretical models. For systems in which the independent timing of the proton and the electron can be achieved, the isotope effects for the kinetically resolved electron and proton events may be measured directly. We anticipate that the data provided from such measurements and the accompanying theories will comprise a powerfully predictive framework, which will be useful in future interpretations of isotope effects in catalytic reactions in enzymes and model systems.

On a second front, in all of the systems described here, the hydrogen bond interface is required to maintain assembly of the supramolecular complex. This construct makes it difficult to assess the effect of pK_a on the coupled electron- and proton-transfer reactions. By placing a network proximal to, yet distinct from, the electron transfer pathway while maintaining independent spectroscopic signatures for electron and proton transfer, the kinetics for the isolated events can be examined as the pK_a of the environment is systematically varied.

New methods for the measurement of electron transfer in hydrogen-bonded systems also loom on the horizon. The study of electron transfer in hydrogen-bonded assemblies has been restricted primarily to photoinitiated reactions. Yet these systems lend themselves to examination by other experimental methodologies as well. For instance, radiolysis, the experimental brethren of photolysis [178], has yet to be applied to the study of electron transfer through hydrogen-bonded interfaces. Electron transfer through hydrogen bonds can also be studied using electrochemical methods. Recently, Whitesides and Rampi have measured the current across junctions formed from juxtaposing two self-assembled monolayers [179]. Comparative measurements of junctions comprised of covalent, ionic, hydrogen bond or van der Waals connections give insight into the relative abilities of these interfaces to mediate electron conductivity and transport.

Finally, with experimental methodologies for PCET measurements in place, and with the knowledge acquired from model studies and accompanying theoretical treatments, future research directions will invariably turn toward defining the mechanisms of coupled electron–proton processes, at a rigorous level, in the complex machinery of biology. Issue 1), of how hydrogen bonds conduct electrons along the pathways of proteins and enzymes, has already been extensively explored [104, 109, 180, 181]. However, other processes, especially those encompassed by case 2), largely have been ignored for a several reasons. Paramount among these are the difficulties of clearly identifying the electron- and proton-transfer pathways in complex biological structures and of isolating the kinetics of the PCET event from

the multitude of other events that accompany biological function, such as conformational dynamics, allosteric regulation, and substrate transport to the active site. Such issues have long been recognized as roadblocks to further advancement in understanding the precise details of PCET in many protein and enzyme mechanisms. For instance, Malmström states in his review of cytochrome *c* oxidase [182], ‘In many ways the situation is disappointing, however. The mechanism deals only with the formal kinetics and the chemical nature of the catalytic intermediates, but it provides no information on the molecular mechanism’. In the area of photosynthesis, the disconnect between intimate mechanistic detail and protein/enzyme function is even more striking. Some 30 years after Mitchell’s initial proposal of proton translocation driven by electron transfer [183], Feher and Okamura succinctly state in their review of bacterial RCs [184] that ‘we do not know from experimental measurements whether electron transfer precedes or follows proton transfer, since these individual steps have not been kinetically resolved’.

Of the impressive PCET systems in biology, ribonucleotide reductase (RNR) provides an attractive “laboratory” for mechanistic study. RNR enzymes catalyze the reduction of the four common ribonucleotides to their corresponding deoxyribonucleotides via a thiyl radical hydrogen-abstraction mechanism [185–187]. The redox pathway for the Class I enzymes has been deduced from docked crystal structures of the R2 [188] and R1 subunits from *E. coli* [189]. The oxidizing equivalent of a tyrosyl radical, Y122, generated at the dinuclear iron center of the R2 subunit, is conveyed to the catalytic cysteine residue C439 in the R1 active site where ribonucleotide reduction occurs [190, 191]. Hole transfer between the R1/R2 subunits is proposed to proceed along the 35 Å, tightly coupled PCET pathway shown in Figure 7, as determined from mutagenesis [192, 193], sequence conservation [194], and docking studies of the individual subunits [189]. As has been discussed [191], the oxidation potential of tyrosyl radical (0.94 V) is insufficient to generate a thiyl radical from cysteine thiol (−1.33 V); thus, only oxidation of a deprotonated cysteine thiolate (−0.77 V) is favored, implicating a PCET mechanism. Recent theoretical studies support this contention by predicting proton and electron synchronization (i.e., hydrogen atom transfer) to be highly favored over electron transfer [195]. These extensive discussions notwithstanding, the PCET pathway shown in Figure 7 has escaped direct experimental investigation. In the context of the thematic focus of this chapter, the pathway is formed from the self-assembly of subunits R1 and R2. Consequently, RNR may be viewed as an extremely complex hydrogen-bonded “supramolecule”. The quantitative measurement of electron and proton transport in supramolecules such as these is one of the formidable challenges confronting PCET studies in the near future.

Figure 7. Proposed proton-coupled electron transfer (PCET) pathway between the R2 and R1 subunits of the *E. coli* ribonucleotide reductase (RNR) complex. The conserved amino acids are shown schematically (*E. coli* numbering).

Acknowledgments

We dedicate this chapter to the memory of Bo Malmström. The National Institutes of Health (GM47274) supported the research presented in this review from our group.

5 Host–Guest and Cage-Type Systems

Luigi Fabbrizzi, Maurizio Licchelli and Angelo Taglietti

5.1 Metal Ions Inside Aza-Crowns

Transition metal ions have a natural tendency to exchange electrons, giving rise to a variety of oxidation states, the relative stability of which can be modified at will by changing the ligand's features. A special versatility can be achieved when the metal is coordinated by a multidentate cyclic ligand, for two main reasons: (i) the coordinating tendencies and the affinity towards a given oxidation state can be modulated by modifying the geometrical features of the molecular framework; and (ii) trapping by the closed and often sterically constrained structure provides kinetical stability to otherwise elusive oxidation states, extending their lifetime in solution [1, 2]. A clear example is provided by the nickel(II) cation which, as a solvated ion, does not show any tendency to release/uptake electrons. However, when coordinated by a cyclic polyamine, Ni^{II} can be oxidized to Ni^{III} —a state which, under particular conditions, can be indefinitely stable. The number of amine donor atoms contained in the multidentate framework has a profound effect on the stabilization on the Ni^{III} state, as expressed by the potential associated with the $\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}}$ couple. More surprisingly, even if the number of donor atoms remains the same, the $E_{1/2}(\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}})$ value can vary significantly with ligand's structural parameters, e.g., ring size [1]. In this connection, Figure 1 displays the values of $E_{1/2}(\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}})$, measured in an MeCN solution, at 25 °C, through cyclic voltammetry studies, for 1:1 complexes with tetramine and pentamine macrocycles and with 1:2 complexes with triamine macrocycles, whose formulae are shown in Chart 1.

As far as quadridentate ligands are concerned, the easiest attainment of the Ni^{III} state, denoted by the less positive redox potential, is observed with the 14-membered macrocycle, **5**, known as cyclam. Both contraction and expansion of tetramine ring atomicity, to 12 and to 16, respectively, makes the potential more positive, thus destabilizing Ni^{III} with respect to Ni^{II} . Moreover, the isomeric 14-membered macrocycle, **6** (isocyclam) stabilizes the Ni^{III} state to a much lesser extent than cyclam. Notice that the two macrocyclic complexes simply differ in the sequence of the five-

Figure 1. Ring size effect on the potential of the $\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}}$ redox change of *n*-dentate poly-aza macrocycles. Points N_4 , N_5 , and N_6 refer to 1:1 complexes with tetra-aza (systems 4, 5, 7, 8; ■), penta-aza (systems 9–11; ●) and hexa-aza (system 12; ◆) macrocycles respectively. Points $2 \times \text{N}_3$ refer to 1:2 metal complexes with tri-aza macrocycles (systems 1–3; ▲). The open square refers to the isocyclam system, 6. $E_{1/2}$ values measured in acetonitrile (0.1 M Et_4NBF_4) at 25 °C.

and six-membered chelate rings: alternating for the cyclam complex (5,6,5,6) and grouped for isocyclam (5,5,6,6). This state of affairs can be qualitatively explained by considering that cyclam has the right size and possesses the correct geometric features to place its donor atoms in the coordination positions required by the Ni^{II} center, thus establishing especially strong coordinative interactions. This raises the energy of the metal-centered HOMO level, and makes the electron release particularly easy. A small modification of ligand's geometric features, as observed with the isocyclam system, seriously alters the intensity of the metal–ligand interactions, thus disfavoring Ni^{III} attainment [3]. Addition of a further donor atom (pentamine macrocycles) does not favor the formation of the trivalent complex [4], nor is stabilization observed with six-coordination in bis-triamine complexes [5]. This behavior may seem contradictory, if one considers that Ni^{III} , d^7 , low-spin, likes octahedral coordination and should therefore prefer ligands providing a number of amine donor atoms larger than four. In tetramine macrocyclic complex (e.g., cyclam and isocyclam), the ligand encompasses the equatorial plane, while axial positions are occupied by solvent (MeCN) molecules. In pentamine complexes, the macrocycle folds in order to put a nitrogen atom in one of the apical sites: this probably induces serious steric constraints and reduces the overall intensity of metal–ligand interactions. On the other hand, in bis-triamine complexes, six amine nitrogen atoms are available for the Ni^{III} beloved six-coordination, but the cyclic nature of the ligand sterically prevents regular octahedral coordination for rings of varying size. In par-

Chart 1. Poly-aza macrocycles of varying size and denticity used in the investigation of the $\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}}$ redox change.

ticular, in 1:2 complexes with a series of triamine macrocycles of varying atomicity (1, 2, 3), the attainment of the trivalent state takes place at a more positive potential than for the 1:1 complex of cyclam (5). In contrast, progressive expansion of the triaza-macrocyclic ring induces only a moderate increase of the $\text{Ni}^{\text{III}}/\text{Ni}^{\text{II}}$ potential (see \blacktriangle in Figure 1). Steric effects associated with six-coordination are emphasized with the hexamine macrocycle 12, whose 1:1 Ni^{III} complex is formed at a particularly high potential [4].

In conclusion, the $\text{Ni}^{\text{II}}(\text{cyclam})^{2+}$ moiety seems the appropriate redox active plat-

form for carrying out electron transfer processes, both inter- and intra-molecular, and to manage two metal oxidation states of comparable stability. This property has been effectively exploited to control intramolecular photoinduced electron transfer in functionalized tetra-aza-macrocyclic complexes which behave as redox switches of fluorescence or luminescent sensors.

A fluorescent fragment can be appended to the Ni^{II} -14-membered tetramine platform, through a convenient metal-template synthesis [6, 7], to give systems **13** and **14**. The fluorescent subunits, a dansyl group (in system **13**) and a 2-naphthalene fragment (in system **14**), have been appended to the cyclam-like framework, through a sulphonamide nitrogen atom inserted in the ring: this atom does not show any coordinating tendencies, and the 14-membered macrocycle exhibits the same coordinating behavior as cyclam. In particular, it allows an easy attainment of the Ni^{III} state.

**13****14**

Let us consider first the behavior of the dansyl derivative. When the metal center is in the divalent state, the dansyl group (*dns*) displays its typical emission properties (band centered at 510 nm in MeCN). However, on oxidation to Ni^{III} , through controlled potential exhaustive electrolysis in an MeCN solution, the emission is fully quenched. Quenching has been ascribed to an electron transfer process from the excited fluorogenic fragment dns^* to the Ni^{III} ion. The occurrence of this process can be accounted for on a thermodynamic basis. In particular, the ΔG° value associated with the dns^* -to- Ni^{III} electron transfer, which can be calculated through the cycle illustrated in Figure 2, is distinctly negative: -1.93 eV. On the other hand, for the Ni^{II} -to- dns^* electron transfer process, a positive value of ΔG° is calculated through the pertinent thermodynamic cycle ($\Delta G^\circ \geq 0.7$ eV; see Figure 2), which accounts for the regular *dns* emission in the Ni^{II} derivative. As a consequence, the light emission by the dansyl fragment can be switched ON/OFF at will, by carrying out consecutive controlled electrolysis experiments on a MeCN solution of **13**: when the potential of the platinum gauze used as a working electrode is set at 0.23 V versus Fc^+/Fc , Ni^{II} is oxidized to Ni^{III} and the fluorescent emission is quenched; when the working potential is set back at -0.07 V versus Fc^+/Fc , Ni^{III} is reduced to Ni^{II} and fluorescence is revived.

A similar behavior has been observed with system **14**, in which the emission of the naphthalene fragment is turned ON/OFF through electrochemical oxidation and reduction processes [7]. Fluorescence quenching/revival of dansyl and naphthalene subunits of systems **13** and **14** can be driven chemically in a MeOH solution through sequential addition of an oxidizing agent ($\text{S}_2\text{O}_8^{2-}$) and of a reducing agent (NO_2^-).

Figure 2. Thermodynamic cycles for evaluating the free energy changes ΔG_{eT}° associated with the intramolecular photoinduced electron transfer processes in system **13** in its oxidized (a) and reduced (b) form. The E^{0-0} quantity, the spectroscopic energy, is obtained from the emission spectrum; the E° values, electrode potentials associated with the given redox change, can be determined through voltammetry experiments. The Coulombic term ($e^2/\epsilon r$) has been considered negligible under the present circumstances.

Systems **13** and **14** represent prototypes of molecular switches of luminescence which are operated through a redox input: the system consists of a luminescent unit (the light bulb of the everyday life) and of a metal-containing redox unit (the true switch) [8]. The ON/OFF situation is achieved when one of the two stable oxidation states of the metal quenches the nearby excited fluorophore and the other does not. In principle, redox switches of luminescence based on an electron transfer mechanism can be obtained by properly assembling a photoactive fragment and a metal-centered redox couple, possibly hosted by a cyclic framework. A further example based on the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox couple will be discussed in Section 5.4.

Luminescence quenching in functionalized macrocycles forms the basis of a class of efficient molecular sensors for transition metals. A recent example is given by system **15b**, in which an anthracene fragment has been appended to the carbon

Scheme 1. The coordinating behavior of diamine–diamide macrocyclic ligands. The coordination of a divalent transition metal M^{II} ($M = Cu, Ni$) involves the simultaneous deprotonation of the two amide groups, with formation of a neutral species.

framework of the 14-membered macrocycle dioxocyclam (**15a**) [9]. Dioxocyclam contains two amine nitrogen atoms and two amide groups and, in its neutral form, displays poorly coordinating tendencies towards transition metal ions. However, in presence of an equimolar amount of a divalent 3d cation (e.g., Cu^{II} , Ni^{II}), at the appropriate pH value, the macrocycle, indicated in the following as H_2L , extrudes two hydrogen ions from the amide groups and simultaneously incorporates the metal, according to equilibrium: $M^{2+} + H_2L \rightleftharpoons [M^{II}(L^{2-})] + 2H^+$ [10]. The structural aspects of the complexation equilibrium are sketched in Scheme 1. In the $[M^{II}(L^{2-})]$ complex, the metal feels the coordination of two amine nitrogen atoms and of two nitrogen atoms belonging to deprotonated amide groups. In each deprotonated fragment, the electrical charge, due to a π -delocalization mechanism, is distributed on nitrogen and oxygen atoms.

The complexation equilibrium is fast and reversible. In particular on addition of acid, each deprotonated amide group uptakes an H^+ , thus losing its coordinating tendencies: as a consequence the metal center is instantaneously extruded from the tetra-aza ring. In this aspect, the behavior of dioxocyclam is totally different from that of the tetramine analogue cyclam, whose complexes display an extreme inertness towards demetallation. In fact, the mechanical resistance to the detachment of the coordinated donor atoms prevents amine protonation, which makes Cu^{II} and Ni^{II} cyclam complexes persist almost indefinitely in strong acidic solutions: for instance, in the case of the $[Ni^{II}(\text{cyclam})]^{2+}$ complex in 1 M $HClO_4$ at 25 °C, a half-life of 32 years has been evaluated [11]. In contrast, decomplexation of a $[M^{II}(\text{dioxocyclamato}(2-))]$ complex in acidic solution does not involve any sterically demanding ligand rearrangement, but simply proceeds through the electron redistribution onto the amide donor groups. In particular, two H^+ ions go to protonate the partially negatively charged oxygen atoms of the deprotonated amide groups, withdrawing any negative charge from the nitrogen atoms and drastically reducing the coordinating tendencies of the macrocycle. As a consequence, the metal ion is released to the solution, while the typical dioxocyclam unit is formed again, through a fast keto-enolic equilibrium, as illustrated in Scheme 2 [12].

Scheme 2. Fast demetallation in acidic solution of $[\text{M}^{\text{II}}(\text{dioxocyclamato}(2-))]$ complexes ($\text{M} = \text{Cu}, \text{Ni}$). The partially negatively charged oxygen atoms of the carbonyl groups are quickly protonated, and the consequent drastic reduction of the coordinating tendencies of the adjacent nitrogen atoms promotes metal extrusion.

The process of fast and reversible pH-driven metal inclusion–extrusion can be easily followed, in the case of **15b** derivative, through the emission of the anthracene fragment covalently linked to the macrocycle. Figure 3 shows the fluorescence intensity, I_F , versus pH profile obtained in the course of spectrofluorimetric titration experiments. First, when an aqueous MeCN solution of **15b** (H_2L), containing excess acid is titrated with standard base, the typical anthracene emission spectrum is not modified over the pH range 3 to 10.5. If the titration experiment is carried out in presence of 1 equivalent of Cu^{II} , at $\text{pH} = 3.6$, I_F begins to decrease sigmoidally,

Figure 3. Spectrofluorimetric titration by standard base of the two-component system **15b**, in aqueous MeCN. (◇), **15b** plus excess acid; (▼), **15b**, plus 1 equiv. of Cu^{II} and excess acid; (▽), **15b**, plus 1 equiv. of Ni^{II} and excess acid.

to be completely quenched at pH = 5.3. Quenching reflects Cu^{II} complexation, and is intrinsically due to the occurrence of an electron transfer process from the divalent metal center to the excited fluorophore, *An**. The *An**-to-Cu^{II} electron transfer is characterized by a distinctly negative ΔG° value: -0.50 eV. If Cu^{II} is replaced by Ni^{II}, an analogous sigmoidal decay of I_F is observed, displaced to the right of about 1 pH unit. The higher pH corresponds to the formation of a less stable complex of Ni^{II} with the dioxocyclamato(2-) subunit with respect to Cu^{II}. Also for Ni^{II}, quenching is due to a fluorophore-to-metal electron transfer, a process fully justified on a thermodynamic basis: $\Delta G^\circ_{ET} = -0.35$ eV.

Interestingly, if the same titration experiment is performed in presence of any other 3d divalent cation (Mn^{II}, Fe^{II}, Co^{II}, Zn^{II}), no fluorescence quenching is observed over the entire 2–12 pH interval. In this connection, it must be noted that deprotonation of the amide groups of the dioxocyclam subunit is an especially endothermic process, which can take place only if the unfavorable heat effect is compensated by the exothermic formation of strong metal–ligand bonds. This situation occurs only with metal ions late in the 3d series, e.g., Ni^{II} and Cu^{II}, but not with cations earlier in the same series. Thus, the anthracene functionalized dioxocyclam system represents a selective fluorescent sensor for Cu^{II} and Ni^{II}, whose signal transduction mechanism is an electron transfer process [13].

5.2 Anions Inside Aza-Crowns

Polyaza macrocycles in their protonated form, either full or partial, are able to interact with anionic species, by establishing noncovalent interactions (both electrostatic and hydrogen bonding). Complexation of anions by synthetic polyammonium molecules has been explored over the past two decades, and several examples of selective recognition of different anionic substrates have been reported [14–22].

Some polyammonium macrocycles such as [24]aneN₆H₆⁶⁺, **16**, and [32]aneN₈H₈⁸⁺, **17**, have the right structural features to include negatively charged

metal complexes such as metal cyanides of the general formula $[M(CN)_6]^{n-}$ ($M = Fe^{II}, Ru^{II}$ with $n = 4$; $M = Fe^{III}, Co^{III}, Cr^{III}$ with $n = 3$) and $[M(bipy)(CN)_4]^{n-}$ ($M = Ru^{II}$, $n = 4$) [14, 23–26]. In the resulting adducts, which have been defined *supercomplexes* [27, 28], the macrocyclic receptor can be viewed as a pre-organized second coordination sphere ligand [29]. The inclusion into the fully protonated polyazamacrocyclic receptors significantly modifies the properties of the anionic complexes and, in particular, their ability to take part in electron transfer processes.

In this connection, metal cyanides included in the polyammonium host are generally characterized by more positive reduction potential values for the M^{III}/M^{II} redox couple. This behavior reflects the higher thermodynamic stabilization of the adduct, with the anion possessing the higher negative charge, $[M^{II}(CN)_6]^{4-}$, in which the metal is present in its lower oxidation state. For example, electrochemical studies showed that $[Fe^{II}(CN)_6]^{4-}$ and $[Ru^{II}(CN)_6]^{4-}$ both form 1:1 adducts with **16** and **17**, and are oxidized more difficultly in the presence of the polyammonium macrocycles than in their absence [30, 31]. The self electron exchange process is reversible and takes place without any dissociation of the supercomplex. The higher stability of adducts of the more negatively charged species accounts for a host–guest interaction that is mainly electrostatic in nature. However, hydrogen bonds between the protonated nitrogens and the nitrogens of the cyanide ligands play an important structural role [26].

$[Fe^{III}(CN)_6]^{3-}$, when included in **17**, is involved in an electron transfer reaction with iodide which cannot take place in the absence of the macrocyclic species. In fact, the $E^\circ(Fe^{III}/Fe^{II})$ value for the hexacyano complex is considerably lower than $E^\circ(I_2/I^-)$, so that the electron transfer from I^- to Fe^{III} center is thermodynamically disfavored. However, in the presence of **17**, in an acidic aqueous solution (e.g., pH = 4.4), the redox potential of Fe^{III}/Fe^{II} couple inside the supercomplex is increased to such an extent that the reaction (see Eq. 1), which is essentially isoergonic, proceeds to an equilibrium situation ($K = 7\ M^{-2}$, at 25 °C).

The kinetics of Eq. 1 corresponds to a first-order process, characterized by a rather low rate constant ($k_{obs} = 8.9 \times 10^{-4}\ s^{-1}$ at 25 °C), whose value increases with increasing temperature. As the inclusion complex forms only when the macrocyclic ligand is fully protonated, on addition of base the adduct dissociates and the exoergonic reaction reverse of Eq. 1 takes place. The thermal reaction provides an example of an electron transfer process which can be switched ON/OFF by a pH change [32].

Flash irradiation with visible light ($\lambda > 400\ nm$) of a thermally equilibrated solution gives rise to an instantaneous increase of the I_3^- concentration, followed by a slow decrease in the dark. Although the extremely short lifetime of the $[Fe(CN)_6]^{3-}$ excited state prevents any type of bimolecular process, a photoinduced electron transfer process is responsible for the increased I_3^- concentration upon irradiation. The positively charged supercomplex forms an ion pair with the iodide anion, so that a very fast electron transfer process can take place following a unimolecular kinetics.

Supercoordination by the polyammonium macrocycle has a thermodynamic effect, as it induces an anodic shift of the $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}$ potential; it has also a kinetic effect on the photoinduced process, through the formation of the ion-pair with iodide.

5.3 Metals Inside Aza-Cages

The template reaction involving $[\text{Co}^{\text{III}}(\text{en})_3]^{3+}$ ($\text{en} = 1,2\text{-diaminoethane}$), formaldehyde and ammonia in an aqueous basic solution affords one of the most celebrated metal-cage compounds, the $[\text{Co}^{\text{III}}(\text{sepulchrates})]^{3+}$, **18**, currently indicated as $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ [33–35]. After sepulchrates synthesis, which remains as one of the most powerful methodologies of preparation of macropolycyclic systems, many different cage complexes have been synthesized by still following a template approach. For example the cobalt–dinitrosarcophagine system, **20**, also known as $[\text{Co}(\text{diNOsar})]^{3+}$, can be obtained by employing the formally triprotic acid nitromethane instead of ammonia (still a formally triprotic acid) [36].

The use of different triprotic acids or more sophisticated bidentate amino-ligands as well as the functionalization of preformed cages has increasingly lengthened the list of metal–azacage complexes available today [37].

Table 1. Rate constants for electron self-exchange rates determined for different Co^{III}/Co^{II} systems in water at 25 °C.

Complex	<i>k</i> (M ⁻¹ s ⁻¹)
[Co(NH ₃) ₆] ^{2+/3+}	10 ^{-7a}
[Co(en) ₃] ^{2+/3+}	3.4 × 10 ^{-5b}
[Co(sep) ₃] ^{2+/3+} , 18	5.1 ^c
[Co(sar)] ^{2+/3+} , 19	2.1 ^d
[Co(diamsar) ₃] ^{2+/3+} , 21	0.5 ^d
[Co(diClasar)] ^{2+/3+} , 22	3.0 ^e
[Co(ClMesar) ₃] ^{2+/3+} , 23	2.4 ^e
[Co(diamchar) ₃] ^{2+/3+} , 24	1.0 ^e

^aFrom Ref. [39]; ^bfrom Ref. [40]; ^cfrom Ref. [38]; ^dfrom Ref. [41]; ^efrom Ref. [42].

Owing to the resistance of the macropolycyclic ligand to detach its donor atoms from the metal, the aza-cage complexes are extremely inert (a feature which accounts for the fanciful, yet funereal names given to the early aza-cages **18** and **20**). As a result, not only the intrinsically substitutionally inert Co^{III} complexes, but also the corresponding substitutionally labile Co^{II} derivatives, display an uncommon sluggishness. Co^{II}–amine complexes usually exchange their ligands on a millisecond time scale, while [Co^{II}(sep)]²⁺ is stable for hours in solution at room temperature, as shown by exchange experiments with ⁶⁰Co²⁺ [33, 38]. The extreme inertness of Co–cage complexes of both oxidation states recommended their use in the study of electron self-exchange processes. The rates of Co^{III}/Co^{II} self-exchange reaction for different cage complexes have been determined polarometrically by observing the change in optical rotation, when mixing the chiral form of one oxidation state, e.g., Λ[Co^{II}(cage)]²⁺, with the enantiomeric form of the other, Δ[Co^{III}(cage)]³⁺, according to Eq. 2.

The values of rate constants measured for complexes **18–24** are reported in Table 1. Noticeably, the self-exchange processes in the cage systems are 10⁷ and 10⁵-fold faster than those determined for [Co(NH₃)₆]^{2+/3+} and [Co(en)₃]^{2+/3+}, respectively. This behavior may be surprising, considering the electronic similarity of hexamine and cage complexes. In addition, one might expect that the insulating aliphatic backbone of the cage could make the electron transfer process even more unfavorable. A proposed explanation of the unusually high self-exchange rate of the [Co(sep)]^{2+/3+} system was referred to the presence of unshared electron pairs on the nitrogen atoms of the caps, which could allow a more direct communication between the metal centers. However, a similar rate value was determined also for the [Co(sar)]^{2+/3+}, which does not contain any capping tertiary nitrogen atom [41]. A further explanation was related to the different hydration of the complex and of the

activated complex. Cage complexes are less hydrated than $[\text{Co(en)}_3]^{2+/3+}$ and $[\text{Co}(\text{NH}_3)_6]^{2+/3+}$ reference systems: thus, the cage complex in the course of the electron transfer process should experience a smaller solvational reorganization, which should favor the self-exchange process. This hypothesis was not confirmed by the studies carried on the bulkier complex **24** for which the rate of the self-exchange process is similar to those determined for other cage systems (see Table 1) [43].

Molecular mechanics calculations have demonstrated that the metal ion encapsulation induces a strain in the ligand (i.e., distortion of the expected bond angles and torsion angles). In contrast, crystallographic investigations have shown that the Co–N bond lengths in $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ and $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$ do not differ greatly from those measured for the corresponding $[\text{Co}^{\text{III}}(\text{NH}_3)_6]^{3+}$ and $[\text{Co}^{\text{II}}(\text{NH}_3)_6]^{2+}$ [38]. In any case, the cage hole appears a little too large for Co^{III} , and a little too small for Co^{II} : the resulting strain in both oxidation states induces a stretching of the Co^{III} –N bonds and a compression of the Co^{II} –N bonds. In this way the $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ – $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$ assembly could be helped towards the transition state, even if no evidence of such a strain effect can be obtained by the ground-state metal–ligand bond lengths [42].

Configurational and conformational effects on the rates of electron exchange process have been determined for some stereo- and dia-stereoisomers of *N*-methyl derivatives of **21** [44].

A further intriguing electron transfer process involving Co–cage complexes refers to the quantitative reaction with O_2 to give H_2O_2 . Usually, the Co^{II} –amine complexes react with O_2 to give Co^{III} –peroxy dimers such as $[(\text{NH}_3)_5\text{Co}–\text{O}–\text{O}–\text{Co}(\text{NH}_3)_5]^{4+}$. However, the tightness and bulkiness of the cage ligand structures prevents O_2 from accessing the encapsulated Co^{II} center, and this precludes formation of the peroxo dimer. This would imply the occurrence of an outer-sphere electron transfer process involving the Co^{II} –cage complex and dioxygen. The rate-determining step of this reaction has been established as the formation of the superoxide intermediate, which subsequently and rapidly reacts with another $[\text{Co}^{\text{II}}(\text{cage})]^{2+}$, to give peroxide (see Eqs. 3 and 4).

Alternatively, superoxide can disproportionate in acidic medium to give H_2O_2 and O_2 . For $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$ the global reaction is very fast and the second-order rate constant is $43 \pm 5 \text{ M}^{-1} \text{ s}^{-1}$ [38, 45]. For other cage systems such as $[\text{Co}^{\text{II}}(\text{amsartacn})]^{2+}$, **25**, the reaction is considerably slower ($k = 0.14 \text{ M}^{-1} \text{ s}^{-1}$). The strikingly different behavior can be accounted for on the basis of the reduction potential value, which is less negative in the case of **25** [45].

Other outer-sphere electron transfer rate constants were measured for reactions between different caged complexes in the Co^{II} and Co^{III} oxidation states, and between some caged complexes and different reducing or oxidizing species such as Cr^{2+} , Eu^{2+} , V^{2+} , U^{3+} , $[\text{Co}(\text{NH}_3)_6]^{3+}$, $[\text{Co}(\text{en})_3]^{3+}$, and $[\text{Co}(\text{bipy})_3]^{3+}$. The spectrophotometrically determined values agree with those calculated by using the

Marcus–Hush model. Agreement is especially tight for the reactions involving the cages, $[\text{Co}(\text{NH}_3)_6]^{3+}$ and $[\text{Co}(\text{en})_3]^{3+}$ [41].

The special features of Co–cage complexes can be exploited in reactions which involve photoinduced electron transfer processes [46–54]. Photoexcitation of Co^{III} complexes in their LMCT band usually leads to an excited state that formally is a Co^{II} species. The subsequent efficient decomposition can be interpreted in terms of lability of Co^{II} complexes. In contrast, in the case of $[\text{Co}^{\text{III}}(\text{cage})]^{3+}$ complexes such as **18**, a radiationless conversion to the ground state (i.e., back electron transfer) strongly predominates over ligand dissociation. In view of the photoinertness of their Co^{II} derivatives, Co^{III} -cage complexes can be used as photosensitizers in electron transfer reactions involving ion-pair systems such as **18**-iodide and **18**-oxalate. As observed for other Co^{III} complexes, **18** forms ion pairs with most anions. The interaction with anionic reducing species such as iodide give rise to an IPCT (Ion-Pair Charge Transfer) adduct, which displays a typical band in the near-UV spectral region. Light excitation into IPCT band causes the promotion of an electron from the I^- in the outer coordination sphere to the Co^{III} ion (see Eq. 5).

In degassed solutions, the first step can be followed either by a back electron transfer which restores the starting ion-pair, or by the separation of the primary photoproducts. In the latter case, **I** is scavenged by I^- ion to yield I_2^- which is able to reoxidize $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$. I_2^- can also undergo a disproportionation reaction affording I_3^- and I^- . As I_3^- can reoxidize $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$, no net reaction takes place.

In the presence of oxygen, the reoxidation of Co^{II} species can follow different routes such as those reported in Eqs. 6 and 7.

In this way, while $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ is regenerated, I_3^- accumulates and the net photoreaction can be described as the oxidation of I^- to I_3^- by dioxygen, photo-assisted by the $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ complex [46].

The ion-pair approach to the design of photosensitizers for electron transfer processes has been followed also in the case of $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ –oxalate system. In a deoxygenated solution, the excitation in the IPCT band of $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ – HC_2O_4^- causes the reduction of $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ to $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$ and the oxidation of oxalate to carbon dioxide. The $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$ complex is a sufficiently strong reductant to reduce H^+ to H_2 at moderately acidic pH values. Thus, when the photoreaction is carried out in the presence of colloidal platinum catalyst, such a reaction indeed occurs, and H_2 evolves from the solution in addition to carbon dioxide. Under such conditions, the overall reaction is the oxidation of oxalate, which plays the role of sacrificial agent, combined with the reduction of water to yield carbon dioxide and dihydrogen, according to Eq. 8.

The turnover of $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$, which plays the role of photosensitizer, is higher than 700 at pH 3.0 [47].

Cage complexes can be also employed as electron relays in the catalyzed photochemical splitting of water. The role of a relay, or electron mediator, is to accept an electron from an excited sensitizer, usually $[\text{Ru}(\text{bipy})_3]^{2+}$, and to use it in the catalyzed reduction of water to H_2 . Actually, the features displayed by $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ and its analogues seem to match well with the properties requested for an ideal relay in such a process: (i) a reversible reduction behavior at a reasonable negative potential ($-0.8 < E^\circ < -0.2$); (ii) good thermal and photochemical inertness; (iii) good kinetic factors for outer-sphere electron transfer reactions (i.e., high self-exchange rate); and (iv) stability under hydrogenation conditions. $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ has been firstly used as a relay in a catalytic cycle involving $[\text{Ru}(\text{bipy})_3]^{2+}$ as a photosensitizer and EDTA as a sacrificial donor, in the presence of colloidal platinum. $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ quenches the excited state of $[\text{Ru}(\text{bipy})_3]^{2+}$ by an oxidative electron transfer to yield $[\text{Ru}(\text{bipy})_3]^{3+}$ and $[\text{Co}^{\text{II}}(\text{sep})]^{2+}$. The Co^{II} derivative reduces water (or better H^+) to H_2 , while the Ru^{II} sensitizer is restored through reaction with EDTA [48, 49]. Although the rate of H_2 production is lower than that determined for the commonly used methylviologen relay, the turnover in the case of $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ is much higher, thanks to its high stability under the reaction conditions [50].

Owing to the great interest in photoreduction reactions, electron transfer processes involving $[\text{Co}^{\text{III}}(\text{cage})]^{3+}$ and polypyridine–ruthenium(II) complexes have been extensively investigated. The rate constants for the quenching process range from 2×10^8 to $1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at 25°C . The yields of electron transfer products range from 0.3 to 1.0. These results are in agreement with the relatively low magnitude of the back electron transfer rate constants (8×10^6 to $8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$), which can be explained in terms of poor coupling of $[\text{Ru}^{\text{III}}(\text{bipy})_3]^{3+}$ and $[\text{Co}^{\text{II}}(\text{cage})]^{2+}$ orbitals. An energy transfer mechanism operating beside the electron transfer has also been postulated to explain the overall quenching process [51]. However, an electron transfer contribution $\geq 95\%$ has been estimated for $[\text{Ru}^{\text{II}}(\text{bipy})_3]^{2+}$ quenching involving $[\text{Co}^{\text{III}}(\text{cage})]^{3+}$ complexes with standard reduction potentials less negative than -0.34 V versus NHE. At more negative potentials, the competition of the energy transfer lowers the efficiency of cobalt–cage system in the water photoreduction cycle. On the other hand, at potential higher than -0.25 V versus NHE, the lack of a thermodynamic driving force makes the rate of H_2 production too low. As a result, only a few $[\text{Co}^{\text{III}}(\text{cage})]^{3+}$ complexes display a good efficiency as electron transfer agents in photoreduction of water by systems containing: (i) $[\text{Ru}^{\text{II}}(\text{bipy})_3]^{2+}$ as a photosensitizer; (ii) EDTA as a sacrificial donor; and (iii) colloidal Pt (dispersed on polyvinylalcohol) as a catalyst. The most effective electron mediator of the series is $[\text{Co}^{\text{III}}(\text{ClSar})]^{3+}$, **26**, which, when compared with the reference system methylviologen, displays an equivalent ability to produce dihydrogen, but higher long-term stability in the photochemical cycles [52].

A two-component system containing both the photosensitizer and the electron relay has been obtained by covalently linking a cobalt–cage subunit to an anthracene moiety, *An*. The system **27** is not fluorescent ($\Phi < 2 \times 10^{-4}$), owing to the occurrence of an intramolecular quenching of the excited anthracene by the Co^{III} complex. Investigations on the photophysical features of **27** (i.e., transient absorp-

tion spectroscopy) have shown that the quenching process can be mainly ascribed to an energy transfer mechanism, and that electron transfer accounts for less than 5 % of total quenching. The contribution of the electron transfer process is very low, but when the system **27** is used under the above-mentioned conditions (EDTA as electron donor and Pt in polyvinylalcohol as catalyst), it is important enough to give rise to a detectable photoreduction and to induce dihydrogen production ($\Phi(\frac{1}{2}\text{H}_2) = 0.01$ at pH = 6.5) [53]. Moreover, the efficiency of the $[\text{Co}^{\text{III}}(\text{sep})]^{3+}$ –anthracene conjugate can be improved by introducing a longer spacer between the aromatic photosensitizer and the metal-containing electron relay [54]. System **28**, unlike **27**, emits the blue fluorescence characteristic of anthracene ($\Phi = 0.003$). This shows that, as expected, the rates of the radiationless deactivation processes (energy and electron transfer) decrease on increasing the length of the spacer. Apparently, the distance dependence effect is more severe for the energy transfer contributing process than for electron transfer process, since for **28** the yield of dihydrogen formation, under the standard conditions of water photoreduction, is higher ($\Phi(\frac{1}{2}\text{H}_2) = 0.14$ at pH = 6.5) than for **27**. A singlet excited state has been invoked as the effective intermediate in the photoreduction process: the state is involved in an intramolecular electron transfer to form a Co^{II} species which quantitatively generates H_2 in the presence of the Pt catalyst, according to Eqs. 9–11.

The study performed on systems **27** and **28** has demonstrated the advantage of the two-component approach to improve the efficiency of photoinduced electron

transfer processes. In fact, whereas an anthracene subunit is an efficient photosensitizer when covalently linked to the molecular relay, it does not work when used as a separate molecule.

5.4 Metals Inside Thia-Crowns

Macrocyclic polythioethers form coordination compounds with many transition metal ions [55] and, owing to their moderate π -acidity (intermediate between that of amines and phosphines), can exert a stabilizing effect on lower oxidation states of the encircled metal [56]. Copper complexes of thiacrowns have been widely investigated, even in view of the fact that they can be considered convenient models in the study of redox properties of cuproproteins (systems whose active site is a copper center bound to the thioether groups of methionine residues [57]).

The coordination of copper ion by macrocyclic quadri- and quinque-dentate thioethers makes the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ reduction process easier, and also increases the rate of the redox self-exchange electron transfer process [55]. For example, $[\text{Cu}(\text{13-aneS}_4)]^{2+}$ undergoes a one-electron reduction at 0.52 V versus NHE [58] (cf. $E^\circ(\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}) = 0.15$ V versus NHE for the aquated ion in water) and the rate constant for the corresponding self-exchange electron transfer is $3 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ [59] (to be compared to $k = 5 \times 10^{-7} \text{ M}^{-1} \text{ s}^{-1}$ for the aquated ion [60]). In this connection, it is interesting to note that blue copper proteins are characterized by relatively high potential values and rate constants for the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ self-exchange ranging between 10^5 – $10^6 \text{ M}^{-1} \text{ s}^{-1}$ [61].

For $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ systems, the electron transfer takes place with a large rearrangement of the inner coordination sphere, as Cu^{II} generally prefers distorted octahedral or square pyramidal environments whereas Cu^{I} likes better a tetrahedral geometry. This consideration implies that, in unconstrained systems, one or two Cu–S bonds must be broken and bond angles must be drastically modified upon Cu^{II} reduction. Therefore, any steric constraint imposed by the coordinated ligand could strongly affect the kinetics of the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ electron transfer process.

Owing to the above-mentioned similarities (redox potential values and rate constants) displayed by blue copper proteins and copper–thiacrown complexes, a systematic study has been performed on these low-molecular weight models in order to establish relationships between structural features and redox properties (in particular the kinetics of the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox change). In this respect, thiacrowns present definite advantages compared to other ligands: (i) the presence of a single type of donor atom (other than possible solvent molecules) in the inner coordination sphere; (ii) no protonation phenomena (which in the case of polyamino ligands makes the study in protic media difficult); (iii) highly positive potentials for the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ couple in aqueous media; and (iv) high stability constants with respect to nonmacrocyclic polythiaethers (about 100-fold higher in water) [58].

A thorough study has been performed on the complexes of macrocyclic polythiaethers (such as **29–34** reported in Chart 2) by using electrochemical techniques

Chart 2. Poly-thia macrocycles of varying size and denticity used in the investigation of the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox change.

(voltammetric and potentiostatic measurements), in order to determine the formal reduction potentials, and by kinetic investigations (stopped-flow spectrophotometric and NMR techniques) on different cross-reactions involving Cu^{II} reduction or Cu^{I} oxidation, in order to measure the rate constants related to the electron transfer processes. The redox potentials determined for copper complexes of **29–34** range from 0.67 to 0.85 V versus SCE (in 4:1 methanol/water mixture; see Table 2) [62]. Cyclic voltammetric studies show that several systems (e.g., [15]aneS₅, **34**) display a reversible behavior both in water and in aqueous solvents, in which a single reduction and a single oxidation peak are observed at different sweep rates and temperature. In other cases (e.g., [14]aneS₄, **31**), the emergence of a second irreversible oxidation peak is observed at a higher potential. The relative intensity of the oxidation peak increases with increasing potential sweep rate and/or with decreasing temperature. This behavior is consistent with the existence of two alternate conformers of the Cu^{I} complex which are reoxidized to the corresponding Cu^{II} species at different potential values. The irreversible process observed at a more

Figure 4. Proposed dual-pathway square scheme mechanism for the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ electron transfer process. (A) and (B) represent the stable forms of Cu^{II} and Cu^{I} complexes, respectively, while the species (C) and (D) represent metastable conformers.

positive potential value corresponds to the oxidation of the less stable conformer. In particular, this process takes place in the time scale of the cyclic voltammetry experiment and is observed only at high potential sweep rate or at low temperature. The redox process can be described with a dual-path, square-scheme mechanism in which the electron transfer step (from or to the copper center) takes place sequentially, rather than concertedly, with a conformational change.

As depicted in Figure 4, **A** and **B** represent the stable conformers of Cu^{II} and Cu^{I} respectively, in the coordination environment closest to their preferred geometry. **C** represents the less stable conformer of Cu^{I} , in an environment close to that of the stable conformer of Cu^{II} , **A**, while **D** represents the less stable conformer of Cu^{II} , whose geometric arrangement is close to that of **B**. According to this scheme, the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox process may take place by either of two pathways (**P1** or **P2**). It derives that the conformational rearrangement could precede or succeed the electron transfer step.

The mechanism depicted in Figure 4 is in accordance with the results obtained by kinetic studies. The rate constants calculated for different reduction reactions involving Cu^{II} -thiacrown complexes are often some orders of magnitude higher than the rate constants determined for the corresponding oxidation process involving Cu^{I} -thiacrown complexes [58]. This discrepancy may result from the different re-organizational barriers experienced by the metal centers in the two oxidation states. It is suggested that the two opposite processes (reduction of Cu^{II} and oxidation of Cu^{I}) proceed through different pathway (**P1** or **P2** in Figure 4). Low-temperature voltammetric measurements (down to -77°C) account for a higher stability of the intermediate species **C** with respect to the intermediate **D** [59]. Therefore, under conditions of low driving force, where all the conformational species are present at the equilibrium, pathway **P1** may be more favored. Such a hypothesis is in accordance with the results of NMR line-broadening studies carried out under equilibrium conditions [63].

On the basis of the above-mentioned experimental evidence, the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox exchange in thiacycrown complexes can be considered as an example of *gated* or *directional* electron transfer [64], as the rate of the conformational change can limit the reaction in one direction only.

X-ray crystallographic studies confirm that severe structural changes accompany the electron transfer process (in particular, at least one Cu–S bond is expected to be broken upon the Cu^{II}/Cu^I reduction), and support the hypothesis that conformational rearrangements influence the rate of overall redox process. For example, reduction of the [Cu^{II}(**31**)]²⁺ complex, in which the metal center and the four sulfur atoms are coplanar in a tetragonal arrangement, requires the inversion of two donor atoms (or a rupture of a Cu–S bond followed by the formation of a Cu–Solvent bond) and a dramatic change in the bond angles to produce the stable tetrahedral conformation preferred by the Cu^I center [65]. In the case of **34**, the Cu^{II} complex displays a distorted square pyramidal stereochemistry and, upon reduction, one of the equatorial Cu–S bond is broken to generate a distorted tetrahedral Cu^I complex with a relative small change in bond angles [66]. As a consequence of the lower conformational barrier, the rate constant for the Cu^{II}/Cu^I self-exchange process is higher in the case of **34** ($k = 2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ [67]) than in the case of **31** ($k \cong 10^4 \text{ M}^{-1} \text{ s}^{-1}$ [68]). Further studies performed on the copper complexes of more rigid thiacycrows such as **35–39** (see Chart 3) have confirmed the importance of

Chart 3. Rigid macrocyclic tetra-thiaethers used in the investigation of the Cu^{II}/Cu^I redox change. All the stereoisomers deriving from different configurations of cyclohexyl rings have been studied.

conformational rearrangements in determining the rate of the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ electron transfer process [69–71]. For the complex containing the system **36**, a three-rung ladder scheme has been proposed instead of the above-mentioned square scheme, in order to consider all the possible conformers (and the corresponding conformational changes) for both Cu^{II} and Cu^{I} species [71].

Recently, it has been hypothesized that the rate for the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ electron transfer could be improved by introducing in the macrocyclic backbone a particular constraint which forces the Cu^{II} ion to a square-pyramidal arrangement. In such a way, the metal ion would be out of the plane formed by sulfur atoms, and the strained S–Cu–S bond angles would nearly approximate the angles of the tetrahedral Cu^{I} species. Among tetra-thia-crowns, the best candidate to verify this hypothesis is [12]ane S_4 , **29**. As its Cu^{I} complex salts is poorly soluble, ligand framework has been properly modified to give **40**.

40

X-ray crystallographic studies have shown that the Cu^{II} complex of **40** exhibits a square-pyramidal geometry (with a water molecule occupying the fifth coordination position), whereas the corresponding Cu^{I} complex displays a tetrahedral geometry with one of the sulfur atoms (the one belonging to the thioxane ring) coordinated to the copper center of another complex molecule. Very significantly, the rate constant for the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ self-exchange process is especially high: $7 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, which represents (at present) the highest value ever observed for a $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ self-exchange process [72]. This example shows that tailor-made ligands can be designed specifically in order to modify at will the kinetics of the electron transfer process involving the $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ redox change.

The $\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}}$ couple inside a tetra-thia-crown coordinating environment has been also employed to build up a photoactive system which displays a switching behavior similar to that already discussed for systems **13** and **14**.

In the two-component system **41** an anthracene moiety has been appended to the [14]ane S_4 framework through an estereal bridge. In a MeCN solution, **41** displays a fluorescence spectrum that is less intense, and much less structured and shifted towards higher wavelengths than that typically observed for anthracene. The spectrum is similar to that of the alkyl esters of 9-anthracenoic acid, and can be ascribed to a charge transfer excited state (An^*_{CT}) [73]. On addition of 1 equiv. of $[\text{Cu}^{\text{I}}(\text{MeCN})_4]^+$ to the solution of **41**, the monovalent cation is incorporated by the tetra-thia ring, but the emission spectrum is not altered. The subsequent addition of an excess of the mild oxidizing agent $[\text{NO}]\text{BF}_4$ makes the solution turn bright blue, due to the formation of the Cu^{II} derivative, and the fluorescence to be completely quenched. Emission measurements at 77 K. allow the fluorescence quenching to be

assigned to a photoinduced electron transfer process from the An^*_{CT} state to the Cu^{II} center—a process that is highly favored from a thermodynamic point of view ($\Delta G^\circ_{ET} = -1.86$ eV). In the case of copper(I) complex, the Cu^I -to- An^*_{CT} electron transfer is not thermodynamically favored ($\Delta G^\circ_{ET} = 0.01$ eV), and no fluorescence quenching is observed [74].

The effect of the metal oxidation state on the emission intensity has been also investigated by performing controlled potential exhaustive electrolysis experiments. When an MeCN, poorly emissive solution of the Cu^{II} complex is reduced cathodically to the corresponding colorless Cu^I species, a strong fluorescence enhancement is observed. As the redox process is fully reversible, fluorescence can be switched ON/OFF at will, by setting the potential of the working electrode at the proper potentials for Cu^{II} -to- Cu^I (ON) and Cu^I -to- Cu^{II} (OFF) changes to take place.

5.5 Anions Inside Zn^{II} –Polyamine-Based Systems

The growing interest for the design of supramolecular systems behaving as sensors for anionic species has prompted the study of multicomponent assemblies in which the anionic guest is recognized by a metal-containing host taking profit of coordinative interactions rather than of electrostatic interactions (which include hydrogen bonding).

In recent years, some examples of fluorescent sensors for anions based on the metal–ligand interaction and operating through a photoinduced electron transfer process have been reported. Following the typical two-component approach, molecular-level fluorescent sensors are designed by covalently linking a light-emitting fragment to the receptor suitable for the envisaged analyte [75]. As a receptor, a coordinatively unsaturated metal center is chosen, which leaves one or more vacant coordination sites available for anion binding. A representative example is provided by the $[M^{II}(\text{tren})]^{2+}$ platform (tren = tris(2-aminoethyl)amine).

The branched tetramine tren is a typical ligand for divalent transition metal cations, and forms fairly stable complexes in aqueous solution [76] ($M^{2+} + \text{tren} = [M(\text{tren})]^{2+}$, $\log K$: Cu^{II} , 18.5; Ni^{II} , 14.6; Zn^{II} , 14.5; Co^{II} , 12.7; Fe^{II} , 8.8), which usually exhibit a trigonal bipyramidal geometry, the fifth vacant coordination site being occupied by a solvent molecule or by a coordinating anion (Figure 5).

Figure 5. The tetra-dentate ligand tren coordinates metal ions according to a trigonal-bipyramidal geometry. The fifth coordination site is available for a solvent molecule or for a coordinating anion.

System **42**, trenAn, which is obtained by appending an anthracene fragment (chosen as fluorophore) to the tetramine framework, is reacted with a metal ion M^{II} to give the $[\text{M}^{\text{II}}(\text{trenAn})]^{2+}$ system, which leaves a position available for anion binding.

Genuine transition metal ions (e.g., Cu^{II}) cannot be used as metal centers for building up a fluorescent sensor based on the trenAn system. In fact, d block metal ions tend to quench any proximate excited fluorophore through either an electron transfer or an electronic energy transfer process [13]. The post-transition cation Zn^{II} could be an acceptable surrogate of 3d metal ions for the following reasons: (i) it forms fairly stable complexes with tren in aqueous solution; and (ii) it cannot be involved in any photoinduced electron transfer process (owing to its absolute redox inactivity) or energy transfer process (due to its closed shell electronic configuration, d^{10}).

Since coordinatively unsaturated Zn^{II} polyamine complexes display a good affinity towards the COO^- group, the $[\text{Zn}^{\text{II}}(\text{42})]^{2+}$ platform was first tested for fluorescent sensing of carboxylate anions. For instance, there is evidence from spectrophotometric titration experiments that $[\text{Zn}^{\text{II}}(\text{42})]^{2+}$ forms a stable adduct with benzoate, in ethanolic solution at 25 °C. However, even after the addition of a large excess of benzoate to an ethanolic solution of $[\text{Zn}^{\text{II}}(\text{42})]^{2+}$, the typical fluorescent emission of the anthracene fragment is not altered at all. Quite interestingly, when a solution of $[\text{Zn}^{\text{II}}(\text{42})]^{2+}$ is titrated with the 4-*N,N*-dimethylamine-benzoate anion, the anthracene emission is progressively quenched: the fluorescence intensity, I_{F} , versus anion equivalents profile corresponds to the formation of a 1:1 adduct, and

Figure 6. An electron transfer process to or from the redox active carboxylate anion coordinated to the metal center is responsible for the quenching of the emission of the photoexcited anthracene moiety in the [Zn(42)]²⁺ system.

the log K value for the $[\text{Zn}^{\text{II}}(42)]^{2+} + \text{RCOO}^- \rightleftharpoons [\text{Zn}^{\text{II}}(42)(\text{RCOO})]^+$ equilibrium is 5.45 (Figure 6). Quenching has to be ascribed to the occurrence of an electron transfer process from the *N,N*-dimethylaniline donor fragment, DMA, to the excited anthracene subunit, An^* . The DMA-to- An^* electron transfer (eT) process is characterized by a negative value of the free energy change ($\Delta G^\circ_{\text{ET}} = -0.4$ eV); on the other hand, molecular modeling indicates that coordination to the Zn^{II} center brings the 4-*N,N*-dimethylamine-benzoate donating fragment close enough to the anthracene subunit to ensure the occurrence of a fast and efficient electron transfer mechanism. Fluorescence quenching is observed also for the titration of $[\text{Zn}^{\text{II}}(42)]^{2+}$ with 4-nitro-benzoate and the log K value for the 1:1 adduct formation is 4.73. In this case, quenching is guaranteed by a thermodynamically favored An^* -to-nitrobenzoate electron transfer process ($\Delta G^\circ_{\text{ET}} = -1.0$ eV). In conclusion, the $[\text{Zn}^{\text{II}}(42)]^{2+}$ coordinatively unsaturated complex barely represents a proper example of host for anionic guests, but it is a good starting point towards the realization of metal-based host systems, in which the recognition event of the envisaged guest is signaled via an electron transfer process favored by the proximity of the redox active anion [77].

Along this line, a receptor system containing two $[\text{Zn}^{\text{II}}(\text{tren})]^{2+}$ subunits, linked together by an anthracene fragment, was designed.

The dimetallic receptor $[\text{Zn}^{\text{II}}_2(43)]^{4+}$ is expected to act as a good and selective host for imidazole-containing substrates. Imidazole (imH) is a protic acid but, owing to its very high $\text{p}K_{\text{A}}$ value (14.4), does not deprotonate in water. However, in the presence of two appropriately positioned metal ions, imH may deprotonate and form the imidazolate ion, im^- , which simultaneously bridges the two metal centers. An aqueous solution containing the dimetallic host $[\text{Zn}^{\text{II}}_2(43)]^{4+}$ and adjusted to $\text{pH} = 9.6$ exhibits the typical anthracene fluorescent emission. On addition of imH, fluorescence is quenched substantially, and the I_{F} versus equivalents of imH profile points towards the formation of a 1:1 adduct ($[\text{Zn}^{\text{II}}_2(43)(\text{im})]^{3+}$, log $K = 3.65$),

whose hypothesized structural arrangement is illustrated in Figure 7. In particular, bridging of the two Zn^{II} centers brings imidazolate close to the anthracene subunit, with a distance of about 3 Å between the two aromatic fragments lying in a coparallel fashion. It is probable that π -stacking interactions are present and contribute to the surprisingly high stability in water of the host-guest adduct. This arrangement favors the occurrence of an electron transfer process from the electron-rich im^- anion to the facing excited fluorophore An^* . Histidine shows a similar behavior, with a $\log K$ value for the 1:1 adduct ($[\text{Zn}^{\text{II}}_2(\mathbf{43})(\text{his})]^{3+}$, $\log K = 2.92$) lower than observed for plain imidazole, probably due to the electrostatic repulsive interactions between the charged metal centers and the ammonium group of histidine [78].

Figure 7. The imidazolate ion bridges the two metal centers of $[\text{Zn}_2(\mathbf{43})]^{4+}$, and an electron is transferred to the facing photo-excited anthracene subunit, causing emission quenching.

A further step in the development of fluorescent sensors based on $[\text{Zn}^{\text{II}}(\text{tren})]^{2+}$ and anthracene fragments is the construction of a cage-shaped host. For example, **44** can be obtained by reacting the ligand **43** with two equivalents of terephthalaldehyde and subsequent reduction of the four imine bonds of the Schiff base.

As previously reported for dicopper complex of cage compound **45** [79], the steric constraints imposed by the polycyclic framework induce clear selectivity effects in the recognition of ambidentate anions. In particular, spectrophotometric titration studies have shown that the $[\text{Cu}^{\text{II}}_2(\text{45})]^{4+}$ receptor gives 1:1 complexes of varying stability with ambidentate anions in aqueous solution. Also the $[\text{Zn}^{\text{II}}_2(\text{44})]^{4+}$ complex, which is stable in aqueous solution over a substantial range of pH, can encapsulate ambidentate anions, to give stable 1:1 inclusion complexes. In particular, by titrating with a standard N_3^- solution an aqueous solution 10^{-4} M in $[\text{Zn}^{\text{II}}_2(\text{44})]^{4+}$ complex buffered at pH 8, a linear decrease of fluorescence is observed until the addition of 1 equiv. of azide. From the titration profile, a value of $\log K$ of 5.8 can be calculated for the inclusion equilibrium.

Fluorescence quenching is ascribed to the occurrence of an electron transfer process from the electron-rich N_3^- ion to the nearby An^* fragment (Figure 8).

Figure 8. The azide anion, when enclosed in the zinc(II) cryptate $[\text{Zn}_2(\text{44})]^{4+}$, causes the quenching of the facing anthracene fragment: an electron is transferred from the electron rich anion to the photoexcited spacer. Inclusion of cyanate anion does not alter fluorescence emission, due to lack of the suitable redox potential allowing electron transfer.

Through molecular modeling, a distance of ca 3 Å can be estimated between the closest nitrogen atoms of N_3^- and carbon atoms of the anthracene fragment, which allows the occurrence of a fast and efficient through-space electron transfer process. When titrating a solution of the $[\text{Zn}^{\text{II}}_2(\mathbf{44})]^{4+}$ complex with a series of inorganic anions (NO_3^- , HCO_3^- , SO_4^{2-} , Cl^- , Br^-), no decrease of fluorescence intensity was observed, even after the addition of a large excess of anion. Moreover, the spectrofluorimetric titration profile of N_3^- was not modified in presence of a 10-fold excess of the anion, indicating a much poorer affinity. The case of NCO^- is different: on addition of NCO^- to the receptor solution, no decrease in I_F was observed. However, the titration profile of N_3^- was remarkably affected by the presence of NCO^- : the greater NCO^- concentration, the less steep the I_F decrease, which indicates the presence of a competitive equilibrium for anion inclusion within the cage. In particular, a $\log K$ of 6.5 can be calculated through competition studies for the NCO^- inclusion equilibrium. Thus, NCO^- has a slightly greater affinity for $[\text{Zn}^{\text{II}}_2(\mathbf{44})]^{4+}$ than N_3^- , but, when included in the cage, due to its lower oxidation potential, it is unable to transfer an electron to the nearby An^* fragment. N_3^- and NCO^- anions have the same shape and similar dimensions ("bite length" of 2.34 and 2.42 Å, respectively): the rather high values of the host–guest formation constants reflect the favorable dimensional complementarity between the host cavity (the Zn–Zn distance) and the anion bite length. The other linear triatomic anion, NCS^- , quenches fluorescence, but a much lower value of $\log K$ for the inclusion is observed, 2.45. In this connection, it must be noted that NCS^- is a one-electron reducing agent of strength comparable to that of N_3^- ($\text{NCS}^{\cdot}/\text{NCS}^-$ potential: 1.62 V versus NHE; $\text{N}_3^{\cdot}/\text{N}_3^-$: 1.33), which accounts for the occurrence of an intra-complex photo-induced electron transfer process and fluorescence quenching. However, the much greater bite length of NCS^- (2.75 Å) should induce an endothermic rearrangement of the cage framework, making inclusion 2200 times much less favorable than for N_3^- [80].

5.6 Cyclodextrins

The attention towards electron transfer processes involving host–guest adducts of cyclodextrins (CDs) has become important with regard to their use as modifiers of organic electrode reactions. CDs, when added to solution or to electrode surfaces, can improve the selectivity of electrochemical synthesis. To elucidate the details of electron transfer reactions of guest molecules complexed inside CDs, the redox behavior of ferrocenecarboxylic acid in presence of β -CD was studied, and this showed that the oxidation of the complexed ferrocenecarboxylic anion, FCA^- , must proceed via the dissociation of the host–guest adduct to form free FCA^- which then transfers an electron to the electrode [81].

The work of Kaifer and colleagues [82a–c] and other researchers [83a,b] on different ferrocene derivatives complexed with β -CD illustrates a similar behavior: the monoelectronic oxidation drastically lowers the host–guest affinity (see Scheme 3).

Scheme 3. Redox control on the β -CD complexation of a ferrocene-carboxylate, Fc-COO^- . β -CD displays a higher affinity for the negatively charged FcCOO^- than for the overall neutral ferrocenium carboxylate, Fc^+COO^- . One-electron oxidation favors the release of the guest to the solution, whereas one-electron reduction induces re-complexation by β -CD.

From a different point of view, oxidation in presence of the β -CD host takes place only on the free ferrocene guest, and no direct oxidation of the complexed guest takes place, suggesting that the electron transfer from the complexed ferrocene guest is in some way disfavored because of some thermodynamic or kinetic effect exerted by the host framework.

Following the same approach, CD complexation of cobaltocenium derivatives was investigated [84]. In this case, the positively charged guest (cobaltocenium) is not bound with a significant stability constant, as the neutral cavity of CD is a good receptor only for neutral substrates. However, monoelectronic reduction to neutral cobaltocene increases the affinity between CD and the neutral guest which forms. The same situation is found using viologens as guests. The one-electron reduction of the dicationic, weakly interacting guest leads to a radical cationic species which is not still strongly bound, whereas two-electron reduction gives a neutral guest which forms a very stable adducts with the β -CD host [85].

A particular emphasis is to be made on these systems: the recognition of ferrocene-based substrates can be switched off by monoelectronic oxidation of the substrate itself, whereas in the case of positively charged guests the binding interaction can be electrochemically activated by either a mono- (for cobaltocenium) or bi-electronic (for viologen) reduction process [86].

Several examples of CDs bearing a photo- or redox-active fragment displaying either electron donor or electron acceptor properties have been prepared during the past decade. In all these systems, the two-component approach was followed, by covalently linking a redox active fragment and a receptor subunit: when a guest with the proper redox potential is complexed, an electron is transferred to or from the redox active moiety appended to the CD.

In 1993, Kuroda and colleagues [87] reported the cyclodextrin-sandwiched porphyrin **46**. This receptor is able to bind quinonic substrates as function of their hydrophilicity (Figure 9). Addition of redox active quinones to an aqueous solution of the host **46** results in fluorescence quenching of the porphyrin moiety, due to the occurrence of a photoinduced electron transfer from the excited fragment of the host to the complexed acceptor guest. ESR studies on irradiated frozen solutions showed the presence of the porphyrin radical cation and of the quinone radical anion. Electron transfer reactions were also studied by means of time-resolved fluorescence spectroscopy, obtaining a clean single exponential decay of the receptor

Figure 9. Inclusion of quinone substrates into the cyclodextrin moiety promotes the occurrence of an electron transfer process from the photoexcited porphyrin fragment to the quinone.

with a τ_s of 3.2 ns, and a biexponential decay for the host–guest adduct. For every complexed guest, the lifetime for the long-lived component is identical to that of the uncomplexed host (3.2 ns), while the second short-lived component is much lower (ranging between 0.5–0.7 ns). From these data, the rate constants of intramolecular electron transfer reactions were calculated to be around 10^9 s^{-1} , a value which was found reasonable for this type of process [87].

In another recent example, a terpyridine fragment has been appended to the lower rim of a β -CD, and a subsequent reaction with $\text{Ru}(\text{ttp})\text{Cl}_3$ yielded the complex **47**, $[(\beta\text{-CD-ttp})\text{Ru}(\text{ttp})][\text{PF}_6]_2$.

When the redox active guest anthraquinone-2-carboxylic acid is added to compound **47**, a partial quenching of about 20 % of the MLCT emission of the ruthenium center of the complex is observed, while no quenching is observed when the same substrate is added to the metal complex in absence of the cyclodextrin receptor. The partial quenching can be then ascribed to the occurrence of an electron transfer process between the guest complexed into the CD cavity and the appended metal center [88].

The same approach was used by Nakamura and coworkers: compound **48** profits from a polypyridyltricarboxylrhenium(I) luminophore, whose luminescence is quenched by addition of *N,N*-diethylaniline (DEA) [89].

The luminescence decay in presence of DEA is fitted by a two-exponential model, with a long-lived component, which is present also on the guest free receptor, and

a short-lived one, which is observed only in the host–guest adduct. The observed luminescence quenching results from the sum of two different mechanisms: (i) a dynamic quenching contribution arising from a diffusional collision between the luminophore and the free substrate in solution, which mainly affects the longer-living component; and (ii) a static quenching contribution which derives from an electron transfer from the donor guest trapped into the CD cavity to the Re complex fixed outside the host cavity. The rate of electron transfer k_{eT} is estimated to be $3.7 \times 10^7 \text{ s}^{-1}$.

A very similar behavior is shown by compounds **49** and **50**: the addition of several sulfonated aromatic guests produces both static and dynamic fluorescence quenching of the dicyanoanthracene moiety appended in different arrangements to the CD host.

Also in this case, the photoinduced electron transfer from the complexed redox active guests to the organic fluorophore appended to the receptor subunit of the host is responsible for the static component of the observed quenching process [90].

5.7 Calixarenes and Related Compounds

Calixarenes, just like CDs, are electroinactive hosts, but the electrochemical properties of redox active substrates can undergo sensible changes when host–guest in-

teractions take place. A representative example is provided by ferrocene inclusion in sulfonatocalixarenes, whose behavior is in some way specular to that of cyclodextrins. Voltammetric experiments have shown that the host interacts more strongly with the oxidized, neutral ferroceniumcarboxylate, $\text{Fc}^+ \text{-COO}^-$, than with the reduced, anionic form of the guest, Fc-COO^- , for which electrostatic repulsions with the negatively charged host should operate. The effect of calixarene addition on peak currents is much smaller than that observed with β -CD, which indicates that the reduced ferrocene guest is not significantly bound to the host [86].

Using neutral or positively charged ferrocene substrates does not change the observed trend. When sulfonatocalixarene is added to ferrocenic substrates such as **51**, **52** and **53**, the half-wave potential associated with oxidation processes is shifted towards more negative values (shifts range between 50 and 120 mV); complexation by the anionic host stabilizes the oxidized, positively charged ferrocenium species, and once again the oxidized species are more strongly bound than the reduced forms. Calixarene complexation also causes a decrease in the apparent diffusion coefficient of the electroactive substrate, due to the greater bulk of host-guest adducts with respect to the corresponding uncomplexed ferrocene derivatives. A current decrease is observed, compared to uncomplexed ferrocene, indicating that complexation of the ferrocenic guests takes place before their oxidation [91].

As far as functionalized calixarenes are concerned, two very close examples of electron transfer reaction between a complexed substrate and a redox active fragment bound to the calixarenic receptor were provided by Sessler's group [92] and by Weiss and Mildbradt [93]. Two calix[4]arenes moieties are linked together by a Zn^{II} porphyrin (Figure 10). When benzoquinone is added to a CH_2Cl_2 solution of compound **54**, quenching of the metalloporphyrin fluorescence is observed. More-

Figure 10. Binding of a quinone to the calixarene compartment of system **54** promotes the occurrence of a Zn^{II} (porphyrin)-to-quinone photoinduced electron transfer process.

over, the Stern–Volmer plot obtained from the steady-state measurements gave a curved line, in contrast with that found with the control compound without the guest units, for which a linear plot was observed. As in the case of cyclodextrins, this behavior is consistent with the excited state of the guest molecule being quenched by both static and dynamic processes. Time-resolved measurements on the empty guest (i.e., in absence of benzoquinone) and on the control compound showed the presence of a monoexponential decay with a lifetime of 1.6 and 1.7 ns, respectively. When benzoquinone is added to the control compound, a monoexponential decay is still observed, displaying a distinctly lower dynamic lifetime, as one might expect for an intermolecular quenching process. Addition of benzoquinone to host **54** results in a decay profile which was fitted with two exponential components: a long-lived component with variable lifetime depending upon substrate concentration, and a short-lived component with a constant lifetime of 700 ps, which is attributed to a quenching process due to an electron transfer from the calixarene- Zn^{II} porphyrin system to the benzoquinone guest. Weiss's compound, which slightly differs in the bridge linking the calixarene receptor and the Zn^{II} porphyrin, showed a similar behavior in a 19:1 THF/water solution.

Following a different approach, both the redox active fragments (the donor and the acceptor) can be placed within a host molecule, thus making an electron transfer possible inside the host cavity. In these circumstances, one might attempt to perturb the electron transfer process through the inclusion of an appropriate guest.

One of the smartest examples of this approach involving a calixarene platform has been provided by Shinkai and colleagues [94]. In this system (**55**), a calix[4]arene brings a pyrene fragment as a fluorophore and a nitrobenzene fragment as an acceptor of electrons, bound via ester groups. System **55** displays a very low fluorescence quantum yield—a feature which can be accounted for considering that the ester groups can rotate freely, thus occasionally bringing the excited fluorophore and the nitrobenzene acceptor moiety very close, and favoring the occurrence of an electron transfer process. Upon addition of alkaline metal salts, fluorescence emission sensibly increases, in correspondence of the formation of a 1:1 host–guest

adduct between **55** and the metal cation. Fluorescence revival is to be ascribed to the ester carbonyl's reorientation towards the inside of the host, to ensure metal binding into the ionophoric compartment. This reorientation drastically reduces the freedom of movement of the electroactive fragments, thus decreasing the efficiency of the electron transfer process from the excited fluorophore to the nitrobenzene acceptor.

A further example of steric control on electron transfer processes involving calixarene hosts has been provided by Ziessel and coworkers who appended one (**56**) or two [$\text{Ru}^{\text{II}}(\text{bpy})_3$] moieties and a *fac*-[$\text{Re}^{\text{I}}\text{Cl}(\text{CO})_3(\text{bpy})$] (**57**) to a calix[4]diquinone [95]. For all the complexes the luminescence quantum yield is very low because of

photoinduced electron transfer occurring from the metal center to the close quinone fragment of the host. This explanation is supported by molecular dynamic simulations showing that when the calixarene moiety exists in a noncone conformation, the redox active fragments can become arranged in a coparallel fashion, which brings them in orbital contact, and makes the electron transfer process very favorable. The addition of Ba^{2+} cations to the rhenium complex **57** induces complete quenching of the residual luminescence: the cation stabilizes by ion pairing the emergent negative charge generated by the electron transfer process, which is therefore made easier. Quite interestingly, addition of Ba^{2+} (but also of many others mono-, di- and tri-valent cations) to **56** leads to a strong restoration of the Ru^{II} complexes luminescence. In this case, the moderately favorable effect exerted by the metal on the electron transfer process is more than compensated by the guest-forced adoption of the cone conformation, which precludes any orbital overlap between the redox active subunits of the host, the quinones and the metal complex, thus reducing the intramolecular electron transfer rate in host **56** from $1.7 \times 10^8 \text{ s}^{-1}$ down to $0.44 \times 10^6 \text{ s}^{-1}$.

Beer, Balzani and coworkers [96] have recently realized an anion sensor based on the same subunits, which operates through an intramolecular electron transfer between an appended luminescent metal complex and a quinone fragment, both included within a calixarene framework. Systems **58** and **59** display a remarkable

**58****59**

emission retrieval effect upon addition of acetate, chloride, and hydrogenphosphate in DMSO solution. The anionic guest complexation within the host cavity once again induces a perturbation of the intramolecular photoinduced electron transfer from the MLCT excited state of the Ru^{II} (**58**) and Re^{I} (**59**) complex to the quinone acceptors of the calixarene.

5.8 Carcerands and Hemicarcerands

The first attempt to perform redox reactions on guest molecules inside hemicarcerand cages was carried out by Robbins and Cram in 1993 [97]. Chemical oxidation with either ceric ammonium nitrate–silica gel in CCl_4 at room temperature or thallic trifluoroacetate in refluxing CCl_4 was performed on hydroquinone guests trapped inside hemicarcerand **60**, thus obtaining the corresponding quinone hemicarceplexes. When the incarcerated quinones are reduced with samarium iodide in

refluxing THF, the corresponding original hydroquinones are obtained without any side reaction, and without hemicarceplex destruction. Under the same conditions, the corresponding hemicarceplex containing nitrobenzene was reduced to the corresponding hydroxylamine in high yield. These reactions demonstrate that electrons can be transferred into and out the interior phase of the host, and that the redox reactions can take place without a direct contact of the guest and the reagent.

Studies on the electrochemical behavior of ferrocene encapsulated in the hemicarcerands **61** and **62**, indicated that encapsulation induces substantial changes in the oxidation behavior of the ferrocene subunit [98]. In particular, encapsulated ferrocene exhibits a positive shift of the oxidation potential of c. 120 mV, probably because of the poor solvation of ferrocenium inside the apolar guest cavity. Lower apparent standard rate constants were found for the heterogeneous electron transfer reactions, compared to those found in the uncomplexed ferrocene under identical experimental conditions. This effect may be due to two main contributions: (i) the increased effective molecular mass of the electroactive species; and (ii) the increased distance of maximum approach of the redox active center to the electrode surface.

**63**

One of the best known examples of electron transfer reactions involving hemicarceplexes is the one investigated independently by Pina, Balzani and colleagues [99] and by Deshayes and coworkers [100]. The latter study is focused mainly on triplet energy transfer, a process which can be mechanistically related to electron transfer [101].

In Pina's work, 2,3-butanedione is trapped inside hemicarcerand **63** to give the corresponding hemicarceplex, and the reactions with several electron donors are investigated in order to elucidate the effect of the encapsulation on the rates of the electron transfer to the triplet excited state of the guest. The determination of phosphorescence quenching lifetimes of free and incarcerated 2,3-butanedione reveals that quenching for uncomplexed 2,3-butanedione occurs at the diffusion-controlled limits for any donor quencher (e.g., amines), whereas in the case of the encapsulated substrate the rate constants are lower (ranging between 3.5×10^4 and $4 \times 10^8 \text{ s}^{-1}$) and display an approximately linear dependence upon the oxidation potential of the external quencher. In particular, rate constants decrease with the

increasing amine resistance to the oxidation. These results indicate that the electronic interaction between external quenchers and the incarcerated biacetyl is very small, due to the shielding effect exerted by the walls of the hemicarcerand.

6 Electron Transfer Processes in Pseudorotaxanes

Margherita Venturi, Alberto Credi, and Vincenzo Balzani

6.1 Introduction

A particularly interesting family of host–guest systems [1] is that in which a linear guest is threaded through the cavity of a macrocyclic host (Figure 1). A compound which exhibits such a supramolecular structure is usually called pseudorotaxane [2], with reference to the name rotaxane (see Volume III, Part 2, Chapter 7) used to indicate the species in which the ring is prevented to dethread by the presence of bulky stoppers at the ends of the linear guest.

As for any host–guest complex, the formation of a pseudorotaxane occurs via a molecular recognition process between two “instructed” [1a] components. It is a thermodynamically controlled self-assembly process, resulting from the spontaneous interaction of stereoelectronically complementary units contained in the thread and macrocyclic components.

Pseudorotaxanes may be involved in electron transfer processes from three different viewpoints: (i) the recognition process between the thread and the macrocycle may result from a charge-transfer interaction, which implies the appearance of characteristic spectroscopic and electrochemical properties; (ii) the pseudorotaxane structure can be dethreaded/rethreaded by chemically, electrochemically, and photochemically induced electron transfer processes, which leads to the concept of molecular machines; and (iii) dethreading/rethreading of pseudorotaxanes can control the occurrence of charge transfer and electron transfer processes, which offers a route to information processing at the molecular level.

6.2 Main Types of Pseudorotaxanes

The formation of host–guest systems may occur as a result of a variety of interactions deriving from the size, shape, and electronic properties of the two partners.

Figure 1. Schematic representation of a pseudorotaxane structure formed from a macrocyclic host and a linear guest.

The most important types of interactions are those involving hydrogen bonding, electron donor/acceptor ability, hydrophobic/hydrophylic character, π - π stacking, ion-ion, ion-dipole, and dipole-dipole forces and, on the side of the strong interaction limit, metal-ligand bond. Usually it is not difficult to understand which is the most important interaction in a given system. It should be noted, however, that in some cases the strongest interaction as far as association is concerned is not that causing the most relevant changes in the properties of the system (e.g., UV-visible absorption, fluorescence and NMR spectra, electrochemical behavior) ongoing from the separated components to the supramolecular structure. This is particularly true for a peculiar host-guest structure like that of pseudorotaxanes.

A number of pseudorotaxanes have been obtained by threading (i) a wire-type component containing electron-acceptor units into a macrocycle which comprises electron-donor units, or, vice versa, (ii) a wire-type component containing electron-donor units into a macrocycle which comprises electron-acceptor units. Some examples are shown in Figure 2: (a) the 1,1'-dibenzyl-4,4'-bipyridinium electron-acceptor dication 1^{2+} threaded into the 1,5-dinaphtho-38-crown-10 **2** [3]; (b) the electron-acceptor aromatic diimide **3** threaded into macrocycle **2** [4]; (c) the acyclic polyether **5** containing a dioxybenzene electron-donor unit threaded into the electron-acceptor cyclobis(paraquat-*p*-phenylene) tetracationic cyclophane 4^{4+} [5]; and (d) the acyclic polyether **6** containing a tetrathiafulvalene electron-donor unit threaded into the electron-acceptor cyclophane 4^{4+} [6]. Although in all these cases a large contribution to the association driving force comes from the electron donor/acceptor interaction, other kinds of interactions—particularly hydrogen bonding—can play an important role, as clearly shown in the cases of pseudorotaxanes constituted by 4,4'-bipyridinium [7a] or 1,2-bis(pyridinium)ethane [7b] threads and crown ether macrocycles.

Several pseudorotaxanes have been obtained by threading wire-type and macrocyclic components carrying complementary hydrogen-bonding functions. For example: (i) a wire-type component containing a secondary ammonium function, such as the *N,N*-dibenzylammonium ion 7^+ , threaded into a suitable crown ether like dibenzo[24]crown-8, **8** (Figure 3a) [8]; and (ii) a wire-type component containing amide functions threaded into a cyclic isophthalamide [2a]. Besides hydrogen bonding, other types of interactions (e.g., ion-dipole, π -stacking) can contribute to stabilize the pseudorotaxane structure.

Figure 2. Some examples of pseudorotaxanes based on charge-transfer interactions: (a) from Ref. [3]; (b) from Ref. [4]; (c) from Ref. [5]; (d) from Ref. [6].

Pseudorotaxanes can also be obtained as a consequence of simple hydrophobic/hydrophilic interactions. This is the case for the since long known species in which a wire-type component (9^{2+}) threads the cavity of α -cyclodextrin **10** (Figure 3b) [9].

A different approach is the metal-based template method [2c], for example starting from a wire (**11**) and a macrocycle (**12**), both containing a phenanthroline unit, and using Cu^+ as a template (Figure 3c) [2c]. Species of this kind are essentially metal complexes, and may have very large formation constants.

6.3 Some General and Particular Aspects of Pseudorotaxane Chemistry

The examples reported above refer to pseudorotaxane species with a 1:1 thread/macrocycle ratio ($[2]$ pseudorotaxanes). It is also possible to obtain species exhibiting different stoichiometric ratios, as illustrated by the $[5]$ pseudorotaxane formed from four cyclophane 4^{4+} components and a $Zn(II)$ -phthalocyanine with appended four polyether substituents carrying π -electron-rich hydroquinone units [11]. Examples of pseudorotaxanes in which a macrocycle (13) is threaded by two linear components (7^+) [12] and a linear component (14) threads two macrocycles (4^{4+}) [13] are shown in Figure 4. Long linear arrays can be obtained by using homoditopic threads and macrocycles (e.g., 15^{2+} and 16 in Figure 5, respectively) [14]. Homogeneous or heterogeneous pseudopolyrotaxanes (Figure 6a) [2a] have also been prepared, as well dendritic ones (Figure 6b) [15]. It should also be noted that

Figure 4. Examples of pseudorotaxanes with (a) 2:1 and (b) 1:2 stoichiometric ratio between thread and macrocycle [12, 13].

in some cases self-assembly between a wire-type species and a macrocyclic ring takes place, but does not lead to the expected pseudorotaxane structure (see, for example the host–guest system formed by **17**⁴⁺ and **18**; Figure 7) [16]. For particular purposes, it is interesting to incorporate in the pseudorotaxane components units capable of exhibiting specific (photochemical, electrochemical, etc.) properties; for example (Figure 8), a thread (**19H**⁺) with an ammonium function and a photoactive anthracene as a stopper [17], a bipyridinium-type wire (**20**⁴⁺) with a photo- and redox-active Ru(bpy)₃²⁺ moiety [18], a crown ether (**21**) incorporating a binaphthyl unit [19], and a cyclophane (**22**⁴⁺) containing a Re complex and two bipyridinium units [20].

Particularly interesting pseudorotaxane species can be constructed by using components which incorporate different recognition functions, such as a thread (**23**⁴⁺) containing ammonium and bipyridinium functions (Figure 9a) [12], or species

Figure 5. An example of a pseudorotaxane formed by complementary homoditopic components [14].

Figure 6. Schematic representation of (a) pseudopolyrotaxanes [2a] and (b) a dendritic pseudopolyrotaxane [15].

Figure 7. Self-assembly between a wire-type compound and a macrocyclic ring leading to an inclusion complex not showing the expected pseudorotaxane structure [16].

Figure 8. Examples of pseudorotaxane components containing units capable of exhibiting specific properties. (a) A wire with an ammonium function and a photoactive anthracene as a stopper [17b]; (b) a bipyridinium-type wire with a photo- and redox-active Ru(bpy)₃²⁺ moiety [18]; (c) a crown ether incorporating a binaphthyl unit [19]; (d) a cyclophane containing a Re complex and two bipyridinium units [20].

[21, 22] (e.g., 24²⁺) consisting of a macrocyclic head and a tail that bring complementary recognition sites (Figure 9b) [21].

If two bulky substituents (stoppers) are placed at the ends of the thread (Figure 10a), a pseudorotaxane is transformed into a rotaxane, a structure that does not allow dethreading because of the presence of the two stoppers. If the thread has relatively bulky substituents since the beginning, the ring can slip through them—a process that requires overcoming of a more or less high activation barrier (Figure 10b) [23]. For such systems, dethreading of the ring is not impossible, but requires overcoming of an even higher activation barrier (Figure 10b), so that under ap-

Figure 9. Examples of pseudorotaxanes formed from components incorporating different recognition functions. (a) A pseudorotaxane with a wire containing a bipyridinium and two ammonium functions [12]; (b) a pseudorotaxane formed by a component containing two complementary recognition sites [21].

appropriate condition (e.g., low temperature) they behave as rotaxanes. This shows that pseudorotaxanes may possess some rotaxane-like character. From another viewpoint, we can say that pseudorotaxanes belong to the fuzzy domain between two sets of extremes (Figure 10c), corresponding to either (i) the two isolated components, or (ii) the assembled rotaxane structure [24]. This is indeed a nice example of fuzzy logic in chemistry—a concept that it is now proving its value for a great variety of industrial chemical processes [25].

6.4 Spectroscopic and Electrochemical Consequences of Charge–Transfer Interactions

The charge–transfer (CT) interaction between electron-donor and electron-acceptor units has several important consequences from the spectroscopic and electrochemical viewpoints [5], and plays a fundamental role as far as the machine-like behavior of these supramolecular species is concerned [26–28].

6.4.1 Absorption and Emission Spectra

The donor/acceptor interaction introduces low-energy CT excited states which are responsible not only for the color of these supramolecular species (due to the presence of broad and weak absorption bands in the visible region), but also for the

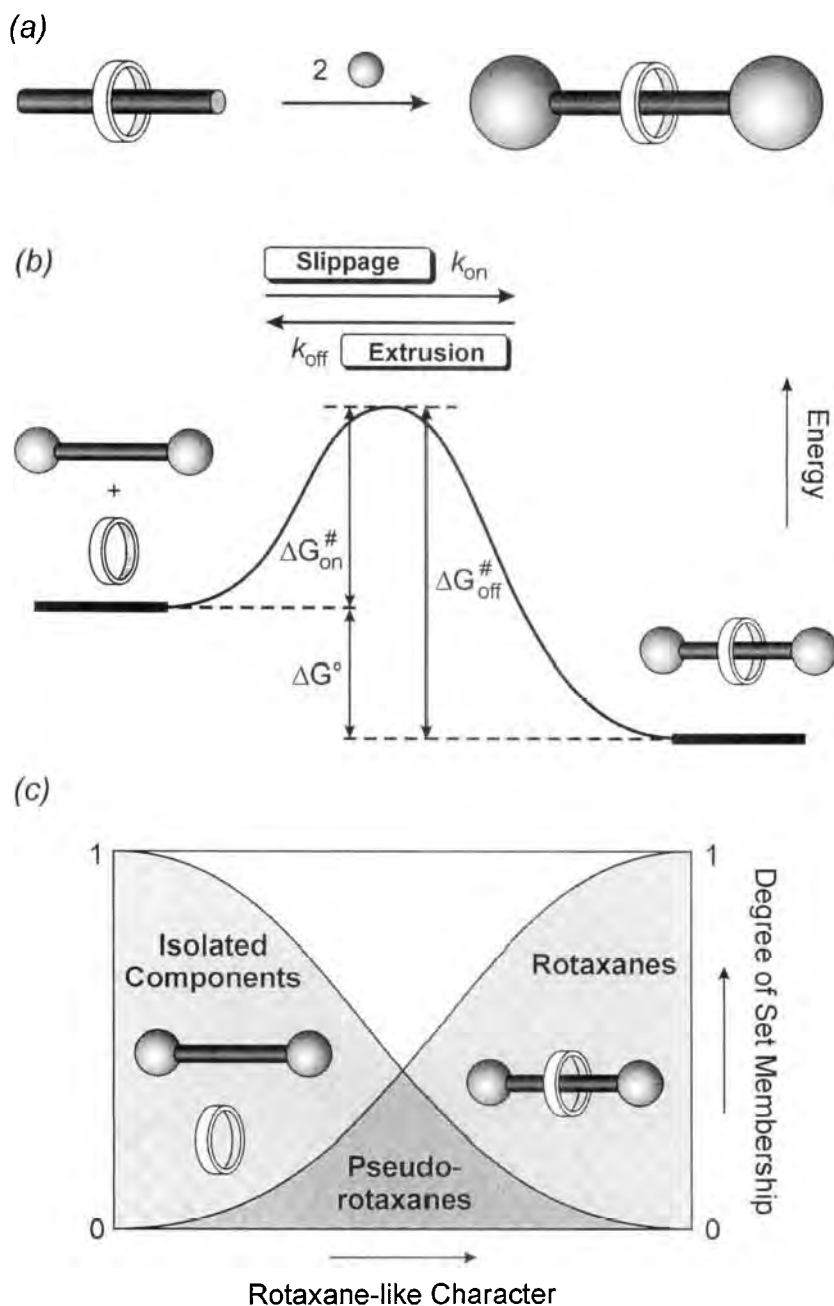

Figure 10. (a) A true rotaxane formed by placing very bulky stoppers at the ends of a pseudo-rotaxane thread. (b) Schematic energy diagram for the self-assembly of rotaxane-like entities via slippage of a macrocycle through relatively bulky stoppers [23]. (c) Schematic illustration showing that pseudorotaxanes belong to the fuzzy domain between isolated components and rotaxane structures [24].

Figure 11. The CT absorption band of pseudorotaxane $[1\cdot 2]^{2+}$ and the absorption and emission bands of its components 1^{2+} and 2 (MeCN, 298 K) [29]. For more detail, see text.

quenching of the potentially luminescent excited states localized on the molecular components (Figure 11). For example [29], both macrocycle 2 and thread 1^{2+} exhibit UV absorption bands, and 2 shows an emission band with $\lambda_{\text{max}} = 330 \text{ nm}$; when the two components are threaded, a new absorption band is present in the visible region ($\lambda_{\text{max}} = 505 \text{ nm}$, $\epsilon = 550 \text{ M}^{-1} \text{ cm}^{-1}$ in acetonitrile solution), and no emission can be seen [29b].

6.4.2 Electrochemical Properties

As far as the electrochemical behavior is concerned, it should be noted that, when engaged in CT interactions, the electron-donor and electron-acceptor units become more difficult to oxidize and to reduce, respectively.

For example, consider again thread 1^{2+} [29], macrocycle 2 [30], and their pseudorotaxane $[1\cdot 2]^{2+}$ (Figure 12). 1^{2+} exhibits two reversible one-electron reduction processes, and macrocycle 2 , which contains two dioxynaphthalene electron-donor

Figure 12. Comparison between the electrochemical behavior of pseudorotaxane $[1\cdot 2]^{2+}$ and its components 1^{2+} and **2** (MeCN, 298 K).

units, shows two (not fully reversible) oxidation processes. When the two components are engaged in the pseudorotaxane structure, the first reduction process of 1^{2+} is displaced by 30 mV towards more negative potentials, whereas the second reduction process is not affected. As far as macrocycle **2** is concerned, in the pseudorotaxane structure its two oxidation processes merge into a two-electron process that occurs at a potential 50 mV more positive than the first oxidation process of the free macrocycle. These results are consistent with: (i) the presence of a CT interaction between the electron-acceptor and electron-donor units; (ii) the occurrence of dethreading upon first reduction of 1^{2+} ; and (iii) the lack of interaction of the two electron-donor units of macrocycle **2** when threaded by 1^{2+} . Dethreading after the first 1^{2+} reduction is confirmed by comparison with the behavior of the analogous rotaxane [23], where also the second reduction process is displaced towards more negative potentials. The fact that the first reduction process of pseudorotaxane $[1\cdot 2]^{2+}$ is reversible indicates that the dethreading/rethreading movement is fast on the electrochemical time scale.

6.5 Electron Transfer Controlling Dethreading/Rethreading Processes

6.5.1 Pseudorotaxanes as Simple Molecular Machines

Dethreading/rethreading of the wire and ring components of a pseudorotaxane is reminiscent of the movement of a piston in a cylinder (see Figure 1), and therefore such a system may be considered as a very simple molecular-level machine. While *natural* molecular-level machines have long been known (our own body can be viewed as a complex ensemble of molecular-level machines) [31], the problem of the construction of *artificial* molecular-level machines was posed for the first time by

Feynman [32] in his famous address *There is Plenty of Room at the Bottom* to the American Physical Society in 1959. In his address, he raised a number of interesting issues (including the need to use cold chemical reactions as energy inputs to make such machines work), and he concluded with the following reflection:

“What would be the utility of such machines? Who knows? I cannot see exactly what would happen, but I can hardly doubt that when we have some control of the re-arrangement of things on a molecular scale we will get an enormously greater range of possible properties that substances can have, and of different things we can do”.

Much better than physicists, chemists are in an ideal position to develop bottom-up strategies towards the design of molecular-level machines, since they are able to manipulate molecules, i.e., the smallest entities of matter that have distinct shapes and properties. Forty years ago, however, the chemical community was not ready to receive Feynman’s stimulation. Only recently, after the development of supramolecular chemistry [1], has the study of artificial molecular-level machines become an important research topic in chemistry [15, 26–28, 33].

Recent investigations in this field have demonstrated, in agreement with Feynman’s suggestions [32], that the input of external energy needed to make such machines work can be provided by different types of chemical reactions. It has also been realized that electrochemical and photochemical processes are the most convenient ones to be used for this purpose.

As we have seen above, several pseudorotaxane structures are stabilized—at least in part—by CT interactions. In these systems, if the CT interactions are destroyed or weakened, dethreading can occur. This can be done by reduction of an electron-acceptor unit or by oxidation of an electron-donor unit contained in the thread or in the macrocycle. In most cases, the CT interactions can be restored by an opposite redox process, which thus promotes a reverse mechanical movement leading to the original structure.

Since the electron transfer processes can be induced photochemically, electrochemically, or chemically, the reported examples have been divided, for the sake of convenience, according to the nature of the redox input.

6.5.2 Photochemically Induced Processes

As we have seen above, CT interactions introduce low-energy excited states responsible for the absorption bands in the visible region (Figure 11). Light excitation in these CT absorption bands formally leads to the transfer of an electron from the donor to the acceptor component (optical electron transfer). As a consequence—particularly when this process leads to formation of charges of the same sign in the two components—one can expect destabilization of the pseudorotaxane structure followed by dethreading. In practice, however, this simple approach does not work because the back electron transfer process is much faster than the separation of the molecular components—a process which requires extended nuclear motions and

solvent rearrangement. In some particular cases [34], laser flash photolysis experiments have suggested that a small fraction of the irradiated pseudorotaxane may undergo dissociation.

In order really to achieve photoinduced dethreading, a different approach has been devised [35, 36], based on the use of an external electron transfer photosensitizer (P) and a sacrificial reductant (Red), as illustrated in Figure 13 in the case of the pseudorotaxane formed by thread **25** and macrocycle **4**⁴⁺. The photosensitizer must be able first, to absorb light efficiently, and second, to have a sufficiently long-lived and reductant excited state, so that its excitation (Process ①) in the presence of the pseudorotaxane will lead (Process ②) to the transfer of an electron to a bipyridinium unit of the cyclophane. The relatively fast back electron transfer from the reduced cyclophane component to the oxidized photosensitizer is prevented by the sacrificial reductant which, if present in a sufficient amount, intercepts the oxidized photosensitizer and regenerates (Process ③) the original photosensitizer. Good candidates for the role of photosensitizer are 9-anthracenecarboxylic acid [37] and metal complexes [38] such as [Ru(bpy)₃]²⁺, while efficient reductant scavengers are triethanolamine and polycarboxylate (e.g., oxalate) anions [39]. Under these conditions, the persistent reduction of a bipyridinium unit of **4**⁴⁺ is achieved and the pseudorotaxane dethreads (Process ④), as evidenced by absorption spectral changes and, more importantly, by the increase in the intensity of the dioxynaphthalene fluorescence, that can only originate from free **25**. Oxygenation of the solution, from which O₂ was initially removed, reoxidizes the cyclophane back (Process ⑤) to the tetracationic form, thereby promoting rethreading (Process ⑥) with **25**, as also shown by the absorption and luminescence spectra.

This strategy has been extended recently to second-generation pseudorotaxanes [**20•2**]⁴⁺ and [**25•22**]⁴⁺ in which the metal-complex photosensitizer (the “light-fueled” motor) has been incorporated (Figure 14) either into the thread [18] or into the ring [20] component. The successful operation of these pseudorotaxanes as molecular machines is the result of first, the appropriate choice of the functional units, and second, their covalent linking into the thread and ring components in order to achieve the correct integration of the needed functions (e.g., receptor ability, redox features, photophysical properties, etc.), the right sequence of processes, and the lack of interference between the active units. As in the case of the molecular machine shown in Figure 13, the dethreading and rethreading motions of the pseudorotaxanes represented in Figure 14 can be triggered by visible light irradiation and oxygenation of the solution, respectively: also, the motions can be easily monitored by means of UV-visible absorption and luminescence spectroscopy. The most important readout signal is the intensity of the dioxynaphthalene fluorescence associated with the free ring **2** (Figure 14a) or free thread **25** (Figure 14b) components. It is worth noting that many deoxygenation–irradiation(dethreading)/oxygenation(rethreading) cycles can be performed on the same solution without any appreciable loss of signal until most of the reductant scavenger is consumed. It should also be stressed that systems which rely on this photosensitizer–scavenger strategy utilize, in addition to light energy, the irreversible decomposition of a reductant scavenger that produces “waste” species. In this regard, the search for efficient molecular machines exploiting “clean”, reversible photochemical reactions (in

Figure 13. The photochemically induced dethreading (MeCN or H_2O , 298 K) of pseudorotaxane $[25\cdot 4]^{4+}$ based on the use of the external photosensitizer P (e.g., 9-anthracenecarboxylic acid) and the reductant scavenger Red (triethanolamine). Rethreading occurs upon oxygenation of the solution [35, 36].

Figure 14. Photocyclable molecular machines based on pseudorotaxanes. In these second-generation systems the “light-fueled” motor (i.e., the photosensitizer, P) is part of the (a) wire-like [18] or (b) macrocyclic component [20]. Red (triethanolamine) is a reductant scavenger. Conditions: (a) EtOH, 298 K; (b) H₂O, 298 K.

Figure 15. The electrochemically induced threading/dethreading processes associated with pseudorotaxane $[26 \cdot 27]^{2+}$ (H_2O , pH 7, 298 K) [44].

other words, machines which use only light as an energy supply) is of fundamental importance.

6.5.3 Electrochemically Induced Processes

Electrochemistry provides a handle on both the input stimuli and the readout signals that are necessary for the operation of molecular machines [33], [40]. A large number of inclusion complexes, in which the association/dissociation of the components can be triggered by changing the oxidation state of the guest or the host, have been investigated [15, 33], [40–42]. Some of the key features of such systems are: (i) the presence of an electroactive unit in one component which exhibits reversible redox processes; and (ii) the effect of the other component(s) on the electrochemical behavior of the component containing the electroactive unit, a property which allows the investigation of the complexation/decomplexation process by, for example, voltammetric techniques.

Cyclodextrins are a class of hosts that are inactive electrochemically, yet can form stable inclusion complexes with a variety of electroactive guests [43]. For instance (Figure 15), it has been found [44] that, while bipyridinium-containing compounds in the dicationic forms (e.g., 26^{2+}) are not bound by β -cyclodextrin (**27**), they interact weakly with the cavity of this host when reduced to their monocationic forms, and give fairly stable pseudorotaxane complexes with **27** when they are finally reduced to their uncharged forms. Similar results have been found [45] for cobaltocenium derivatives; these do not interact with cyclodextrins, yet become good guests for inclusion in **27** upon one-electron reduction to yield the neutral cobaltocene. Ferrocene and its derivatives exhibit [46] the opposite behavior, that is, they are strongly bound in their most stable oxidation state, which corresponds to uncharged species, whereas they are not bound in the oxidized state. These features have been exploited recently to construct dendrimers (see Volume III, Part 2, Chapter 9) that display redox-controllable multisite complexation of **27**, on account of the fact that the dendrimers contain up to 16 ferrocene units [47] or up to 32 cobaltocenium units [48] on their peripheries. Such dendrimers form very large supramolecular architectures that can be either broken apart or assembled by redox inputs. Similar investigations have been carried out on calixarenes, another important class of redox-

inactive receptors [49–51]. However, in contrast with cyclodextrins, the binding to calixarenes becomes stronger on increasing the charge on the guest. This result has been exploited [50] to design a three-component supramolecular system, in which an electroactive guest can choose reversibly between two macrocyclic hosts, depending on its oxidation state [52].

One of the most extensively studied receptors in recent years has been the cyclophane 4^{4+} . It constitutes a very efficient host for a wide variety of electron-donating guests [2b,d,e,i]. Since it is redox-active [5, 53], its binding ability can be subjected to electrochemical control. The tetracationic cyclophane 4^{4+} shows two bielectronic reduction processes, the first one corresponding to the uptake of the first electron by each of the equivalent bipyridinium units, and the second one to the subsequent reduction of radical cations to neutral units. When 4^{4+} is threaded by a component containing an electron-donor unit, as a consequence of the CT interaction (see above), the half-wave potential associated with the first reduction process is shifted to more negative values. The fact that this cyclophane exhibits another reduction process at more negative potentials is very important, as has been pointed out in the case of 1^{2+} , since it can be used to monitor the occurrence of decomplexation induced by the first two-electron reduction [15, 33/]. For instance, in the presence of an excess of a thread-like compound containing a dioxybenzene unit (**5**), the potential value for the first bielectronic reduction of 4^{4+} is shifted cathodically, while the second reduction process is practically unaffected [5]. This observation is consistent with formation of a pseudorotaxane between the cyclophane and the thread (Figure 2c), and also dethreading of the pseudorotaxane upon two-electron reduction of the 4^{4+} host, so that the second two-electron reduction process reflects that of the free host. The occurrence of the dethreading process is not surprising, because reduction of the electron-acceptor component weakens the CT interaction that helps to hold together the components of the supramolecular architecture. Since all these processes are reversible, oxidation of the reduced cyclophane back to 4^{4+} affords the original pseudorotaxane. In principle, it is also possible to obtain useful information on the occurrence of dethreading/rethreading processes from the electrochemical behavior of the electron-donor guest, which is not exactly the case for dioxybenzene unit [23].

More interesting are pseudorotaxanes wherein both the cyclophane and thread components exhibit chemically reversible redox processes, as in the case of the complex of 4^{4+} with tetrathiafulvalene (TTF) [6, 54] and related threads like **6** (see Figure 2d) [6, 55]. With such an improvement in design it is possible not only to monitor the formation of the supramolecular species by studying both the reduction of the electron-acceptor component and the oxidation of the electron-donor one, but also to control the dethreading/rethreading process in a dual-mode (reductive and oxidative fashion). The molecular thread **6**, obtained by linking a TTF unit with two polyether chains (Figure 16), forms a very stable ($K = 5 \times 10^5 \text{ M}^{-1}$ in MeCN) pseudorotaxane with 4^{4+} [55b]. Although the TTF unit in **6** retains the same electron-donor power of plain TTF, as revealed by comparing their voltammograms, the K value for the $[6 \cdot 4]^{4+}$ pseudorotaxane is 50 times higher than that for the TTF complex. This result indicates that the presence of the polyether chains strengthens the association because of the hydrogen bonding between the oxygen

Figure 16. The electrochemically induced dethreading/rethreading processes associated with pseudorotaxane [6•4]⁴⁺ and the absorption spectra recorded (MeCN, 298 K) before oxidation (top) and after oxidation (center) or reduction (bottom) [6].

atoms in the chain and the hydrogen atoms in the α -positions with respect to the nitrogen atoms of the bipyridinium units. This cooperative interaction is extremely important in improving the on/off switching. It has been shown [6] that reversible dethreading/rethreading cycles of the $[6\bullet 4]^{4+}$ pseudorotaxane (as well as of the analogous complex with TTF) can be performed either by oxidation and successive reduction of the electron-donating thread, or by reduction and successive oxidation of the electron-accepting cyclophane. Such processes are accompanied by pronounced spectral differences (Figure 16) that can be followed easily by the naked eye, since the solution changes color from the emerald green typical of the pseudorotaxane to either brown or deep blue upon oxidative or reductive dethreading, respectively. This unique behavior makes such a system appealing for the construction of electrochromic display devices and, since its input(electrochemical)/output(color) characteristics correspond to those of the XNOR (eXclusive NOR) logic operation [6], for the design of molecular-level logic gates [56, 57]. Moreover, the voltammetric behavior on oxidation of this system is scan-rate dependent [58], indicating that the dethreading/rethreading processes (Figure 16), associated with the redox steps of the TTF unit, take place on the time scale of the electrochemical experiment.

The supramolecular complex composed (Figure 17) of the enlarged tetracationic cyclophane 17^{4+} and the ferrocene-based thread **18** has been studied recently with the aim of developing new dual-mode switchable systems [16]. This tetracation is an electron-acceptor cyclophane related to 4^{4+} ; however, while the cavity of 4^{4+} is ideal for accommodating aromatic rings, that of 17^{4+} is perfect for hosting ferrocene [59]. By means of absorption and electrochemical experiments, it has been found [16] that the $[18\bullet 17]^{4+}$ complex, which interestingly does not adopt a pseudorotaxane geometry, can be dethreaded reversibly (Figure 17) either by oxidation/reduction of the ferrocene unit of **18**, or by reduction/oxidation of the bipyridinium units of 17^{4+} .

A three-component supramolecular system, composed (Figure 18) of TTF (which can exist in three stable forms, namely, TTF, TTF^+ , and TTF^{2+}) and two hosts, specifically the electron-accepting cyclophane (4^{4+}) and the electron-donating crown ether **2**, has also been investigated [30]. In its role of an electron donor, TTF forms, with 4^{4+} , a 1:1 inclusion complex [60] which can be dissociated/reassociated reversibly by cyclic oxidation/reduction of TTF [6, 54], while TTF^{2+} acts [30] as an electron acceptor, giving a 1:1 inclusion complex ($K = 4 \times 10^3 \text{ M}^{-1}$ in MeCN at 298 K) with **2**. By contrast, TTF^+ is not bound by either of the two hosts. When the electrochemical potential applied to the solution becomes more positive than +0.4 V versus SCE, TTF is oxidized to the radical cation and the $[TTF\bullet 4]^{4+}$ complex disassembles, giving three essentially noninteracting species. Further one-electron oxidation of TTF^+ to TTF^{2+} at potentials more positive than +0.7 V versus SCE leads to the insertion of the dication into the cavity of **2**. Since both oxidized forms of TTF are stable, the initial state can be restored by subsequent reduction. This system (Figure 18) can therefore be switched reversibly between three distinct states by exercising electrochemical control upon the guest behavior of TTF [61]. The fact that the three states have different colors, coupled with the ease of their electrochemical interconversion, renders this supramolecular system suitable for electrochromic applications. Moreover, as discussed below (Section 6.6.4), this sys-

Figure 17. The decomplexation/recomplexation of the inclusion complex $[18 \cdot 17]^{4+}$ upon electrochemical reduction or oxidation (MeCN, 298 K) [16].

tem could form the basis for the construction of molecular devices in which energy transfer or electron transfer processes between selected components can be controlled [30].

In suitably designed compounds, an intramolecular pseudorotaxane structure can be obtained. An example is given by compound 28^{4+} , which contains a 4^{4+} -type cyclophane covalently linked to a dioxynaphthalene group by a polyether chain [36, 62]. In solution, the tail threads through the cavity of its own head, positioning the dioxynaphthalene group between the two bipyridinium units of the cyclophane (Figure 19). Consistently, the absorption spectrum recorded in MeCN at 298 K of *in-28* $^{4+}$ shows a band at 515 nm in the visible region, arising from CT interactions between the dioxynaphthalene group and the sandwiching bipyridinium units. Such an absorption band is also shown by a model self-complexed system [36] bearing a bulky stopper at the end of the tail. The stopper prevents dethreading of the tail, and so this model compound can exist only in a self-complexed conformation. The similarities between the absorption spectra of *in-28* $^{4+}$ and of this model compound

Figure 18. Redox switching between the complexes $[TTF \cdot 2]^{2+}$, incorporating the macrocyclic polyether **2** and the dication TTF^{2+} , and $[TTF \cdot 4]^{4+}$, composed of the tetracationic cyclophane 4^{4+} and TTF (MeCN, 298 K) [30].

indicate that *in-28* $^{4+}$ also exists completely in its self-complexed conformation in solution. The cyclic voltammogram of *in-28* $^{4+}$ shows two reversible two-electron reduction waves. The first one (-0.35 V versus SCE) corresponds to the simultaneous addition of one electron to each of the two bipyridinium units, and the second one (-0.71 V) corresponds to the simultaneous addition of a second electron to each of the two bipyridinium units. A model tetracationic cyclophane that does not incorporate the dioxynaphthalene tail undergoes two consecutive two-electron reduction processes at -0.29 and -0.70 V, respectively. Thus, the first reduction process occurs at a more negative potential in the case of *in-28* $^{4+}$, while the second reduction process occurs at the same potential in both compounds. These observations indicate that the dioxynaphthalene group of *in-28* $^{4+}$ is sandwiched (Figure 19) initially between the two bipyridinium units, making their first reduction more difficult. However, after the addition of one electron to each of the two bipyridinium units, the dioxynaphthalene unit is expelled from the cavity of the tetracationic cyclophane and the second reduction process is not affected by the presence of the electron-rich unit [36].

6.5.4 Chemically Induced Processes

The assembly of complexes based on electron donor/acceptor interactions can also be controlled by means of redox stimuli provided by the addition of oxidants and

Figure 19. Electrochemically induced dethreading/rethreading of the self-complexing compound **28**⁴⁺ (MeCN, 298 K) [36].

reductants. The inclusion complex [TTF•**4**]⁴⁺ discussed above [6, 54], formed between the electron-acceptor cyclophane **4**⁴⁺ and TTF, as well as pseudorotaxanes [6, 55] composed of **4**⁴⁺ and thread-like species containing a tetrathiafulvalene unit like **6**, can be disassembled [3, 6, 55] into their free components by oxidation of the TTF unit to its radical cation with one equivalent of Fe(ClO₄)₃ in MeCN or aqueous solution. The one-electron oxidized form of the TTF unit is stable in such conditions, and can be reduced back to its neutral form by adding a stoichiometric amount of ascorbic acid. The reduction results in the insertion of the TTF unit into the tetracationic cyclophane. Dethreading can also be achieved by adding *o*-chloroanil, which forms an adduct with the TTF unit; upon addition of Na₂S₂O₅ in the presence of water, *o*-chloroanil is reduced, affording the original complex or pseudorotaxane [55b]. Such dethreading/rethreading processes can be easily monitored by UV-visible absorption spectroscopy since first, the system shows a broad absorption band with a maximum around 850 nm, ascribed to the CT interaction between the electron-rich TTF unit and the electron-poor bipyridinium units of **4**⁴⁺, and second, the neutral and cationic forms of the TTF unit exhibit very different absorption features.

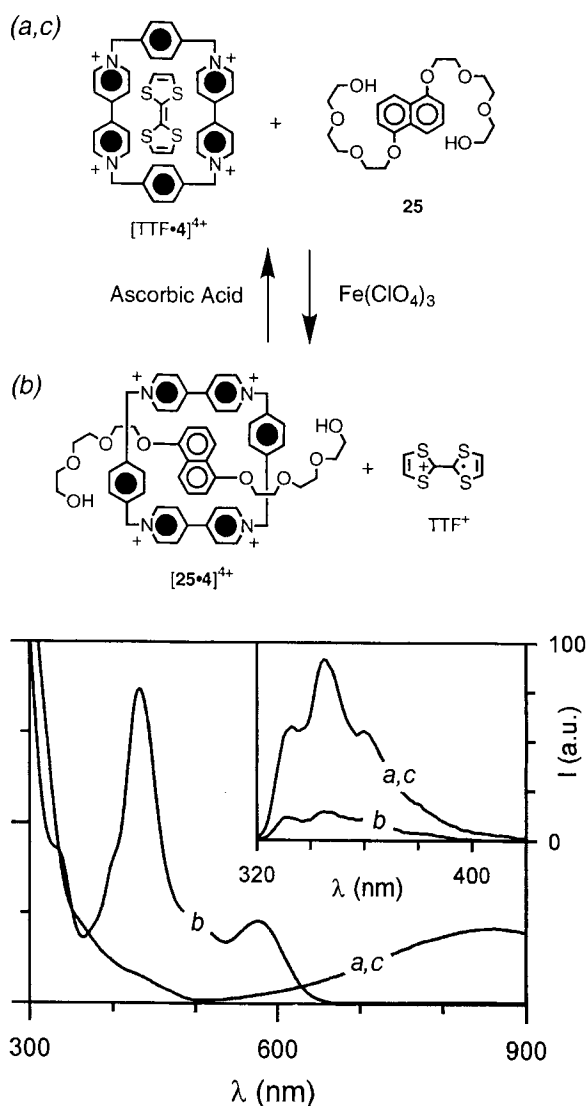

Figure 20. Top: the chemically induced interchange of guests **25** and TTF into the cavity of cyclophane **4**⁴⁺. Bottom: absorption and (inset) fluorescence ($\lambda_{\text{exc}} = 295 \text{ nm}$) spectra of: (a) a $5 \times 10^{-5} \text{ M}$ aqueous solution (298 K) of [TTF•4]⁴⁺ and **25**; (b) the same solution after addition of 1 equiv. of Fe(ClO₄)₃; (c) solution (b) after addition of 1 equiv. of ascorbic acid [3].

A supramolecular system has also been devised in which it is possible, by means of chemical stimuli, to select which one of two guests enters a macrocycle's cavity and to interchange reversibly the two guests (Figure 20) [3]. Addition of the thread-like compound **25**, which contains a electron-rich dioxynaphthalene unit, to an aqueous solution of the [TTF•4]⁴⁺ complex affects neither the CT absorption band characteristic of the complex nor the strong fluorescence band of the dioxynaphthalene-based thread (curves *a* in Figure 20), indicating that this thread does not displace TTF from inside the macrocyclic host. On addition of a stoichiometric

amount of $\text{Fe}(\text{ClO}_4)_3$ (with respect to TTF), the absorption bands of the radical cation TTF^+ are formed, and the CT band of $[\text{TTF} \cdot \mathbf{4}]^{4+}$ disappears, while the fluorescence band of the dioxynaphthalene-based species is substantially quenched (curves *b* in Figure 20). These results show that oxidation causes expulsion of TTF^+ from $\mathbf{4}^{4+}$ and its replacement by the dioxynaphthalene-based thread. On subsequent addition of ascorbic acid, the system returns to its initial state (curves *c* in Figure 20).

The 2,7-dibenzylidiazapyrenium dication $\mathbf{29}^{2+}$ has a strong affinity for aliphatic amines, giving rise to charge-transfer complexes. This property can be exploited to dethread the pseudorotaxane formed by $\mathbf{29}^{2+}$ with the 1,5-dinaphtho-38-crown-10 macrocycle $\mathbf{2}$ (Figure 21) [63]. Macrocycle $\mathbf{2}$ also forms a pseudorotaxane with the 1,1'-dibenzyl-4,4'-bipyridinium thread $\mathbf{1}^{2+}$ [3]. On mixing macrocycle $\mathbf{2}$ with threads $\mathbf{29}^{2+}$ and $\mathbf{1}^{2+}$ in $\text{CH}_2\text{Cl}_2/\text{MeCN}$ 9:1 (v/v) solution, the cavity of the macrocycle is occupied by the $\mathbf{29}^{2+}$ thread, since the stability constant of pseudorotaxane $[\mathbf{29} \cdot \mathbf{2}]^{2+}$ is about two orders of magnitude larger than that of $[\mathbf{1} \cdot \mathbf{2}]^{2+}$. Upon addition of excess hexylamine, strong spectral changes are observed, indicating quantitative formation of the adduct between $\mathbf{29}^{2+}$ and the amine, whereas luminescence measurements show that the pseudorotaxane $[\mathbf{1} \cdot \mathbf{2}]^{2+}$ is formed in amount corresponding to its stability constant (Figure 21) [3]. The process can be fully reversed by addition of acid. This interchange process is similar to the redox-driven [3] or metal ion-driven [64] interchange between two electron-donors guests into the cavity of the electron-acceptor cyclophane $\mathbf{4}^{4+}$ and to the exchange of two macrocycles on changing the redox properties of the guest species [30] (see Section 6.5.3).

Figure 21. Schematic representation of the reversible interchange between two threads in a pseudorotaxane structure upon amine/acid stimulation ($\text{CH}_2\text{Cl}_2/\text{MeCN}$ 9:1 (v/v), 298 K) [3].

6.6 Electron Transfer Controlled by Dethreading/Rethreading Processes

6.6.1 Pseudorotaxanes and Information Processing

In the previous section we have described pseudorotaxane systems in which electron transfer inputs govern dethreading/threading processes, opening the way to the control of nuclear movements (molecular machines). In this section, we will see that, in their turn, nuclear movements induced by an appropriate stimulation (e.g., an acid/base reaction) can govern the occurrence of electron transfer processes or CT interactions. This aspect of pseudorotaxane chemistry can be exploited for the construction of electronic devices for information processing at the molecular level.

6.6.2 Plug–Socket Systems

Crown ethers and ammonium ions can give rise to pseudorotaxanes under acid/base control [8]. Recently, luminescent units such as dioxybenzene [12, 17], dioxynaphthalene [12, 17b], binaphthyl [19, 65], and anthracene [17], have been incorporated into crown ethers or ammonium ions, in order to study the photoinduced processes that take place within pseudorotaxanes that can be threaded/detreaded by acid/base inputs. An example dealing with energy transfer, but that can be easily extended to electron transfer, is shown in Figure 22 [19]. The absorption and fluorescence spectra of a CH_2Cl_2 solution containing amine **30** and the crown ether **21** indicate the absence of any interaction between the two compounds. Addition of a stoichiometric amount of $\text{CF}_3\text{SO}_3\text{H}$ with respect to the amine causes profound changes in the fluorescence spectrum of the solution, particularly as a result of the quenching of the luminescence of **21**, and also the sensitization of the luminescence of **30** upon excitation with light absorbed exclusively by the crown ether. These observations are consistent with the formation of a pseudorotaxane-type adduct wherein very efficient energy transfer takes place from the binaphthyl unit of the crown ether to the anthracenyl group incorporated within the dialkylammonium ion. Such a pseudorotaxane can be disassembled by the subsequent addition of a stoichiometric amount of base, thereby interrupting the photoinduced energy flow, as indicated by the fact that the initial absorption and fluorescence spectra are restored. Such systems can be viewed (Figure 22) as molecular-level plug–socket devices, since they are characterized by chemically controlled, reversible *plug in/plug out* behavior, and photoinduced energy transfer in the *plug in* state. Interestingly, the *plug in* process does not take place when a plug component incompatible with the size of the socket, such as the benzyl-substituted amine **19**, is employed [19]. As mentioned above, extension to photoinduced electron transfer processes is straightforward. Furthermore, since the enantiomeric recognition of ammonium ions by crown ethers containing binaphthyl is a well-known property [65], stereoselective *plug in/plug out* systems can also be designed.

Interestingly, a similar system, where the chemical stimuli provided by counterions are employed to achieve switching, has also been reported [66].

Figure 22. The reversible acid/base-driven threading/dethreading motions of pseudorotaxane $[30H \cdot 21]^+$ (CH_2Cl_2 , 298 K) [19]. In the threaded structure, energy transfer can take place from the binaphthyl unit of the crown ether to the anthracenyl group of the dialkylammonium ion. The acid-driven threading of compound **19**, incorporating a bulky benzene group, through the macrocyclic cavity of **21** does not occur. Such systems can be viewed as molecular-level plug–socket devices.

6.6.3 Extensions

The plug–socket concept has been developed to design a molecular-level extension. The investigated [67] system (Figure 23) consists of macrocycles **2** and 32^{2+} , the latter carrying a $Ru(bpy)_3^{2+}$ moiety, and thread $31H^{3+}$ which contains two different recognition sites, namely an ammonium and a bipyridinium function. Thread $31H^{3+}$ can undergo hydrogen-bonding interactions with macrocycle 32^{2+} and acceptor–donor interactions with macrocycle **2**. Once the two connections have been established, light excitation of the $Ru(bpy)_3^{2+}$ moiety of macrocycle 32^{2+} causes the

Figure 23. A molecular-level extension. Thread 31H^{3+} can undergo a hydrogen-bonding interaction with macrocycle 32^{2+} and an acceptor–donor interaction with macrocycle **2** (MeCN, 298 K). Once the two connections have been established, photoinduced electron transfer occurs from the excited state of the $\text{Ru}(\text{bpy})_3^{2+}$ moiety of macrocycle 32^{2+} to the bipyridinium unit hosted in macrocycle **2** [67].

transfer of an electron to the bipyridinium unit hosted in macrocycle **2**. Extensions containing a plug and a socket instead of two plugs, in which an electron is transferred from a socket to a remote plug, have also been designed.

6.6.4 Logic Gates and Switches

Machine-like movements induced by external stimuli in pseudorotaxanes correspond to a binary logic behavior. As mentioned above, this can result in systems that perform as molecular-level logic gates. An interesting example of a pseudorotaxane system behaving as an XOR logic gate is illustrated in Figure 24 [56]. Pseudorotaxane $[29 \cdot 33]^{2+}$, composed by the diazapyrenium thread 29^{2+} and the 2,3-dinaphtho-30-crown-10 macrocycle **33**, can be disassembled by aliphatic amines because of the previously discussed formation of an adduct between the diazapyrenium thread and amines [63]. This process can be coupled with the possibility

Figure 24. Schematic representation of the dethreading/rethreading pattern of pseudorotaxane $[29\cdot 33]^{2+}$ ($\text{CH}_2\text{Cl}_2/\text{MeCN}$ 9:1 (v/v), 298 K) which corresponds to an XOR logic function [56].

of dethreading the same system by protonation of the crown ether in nonpolar solvents. It has been shown [56] that $[29\cdot 33]^{2+}$ in $\text{CH}_2\text{Cl}_2/\text{MeCN}$ 9:1 (v/v) can be dethreaded upon addition of $n\text{-Bu}_3\text{N}$ and assembled again by adding protons. The same result can be obtained by reversing the order of the two chemical inputs; that is, dethreading can be achieved by protonation of the crown ether's cavity, and rethreading can be obtained by the addition of $n\text{-Bu}_3\text{N}$. All these processes are accompanied by on/off switching of easily monitorable changes in the absorption and luminescence spectra, particularly of an intense fluorescence band, characteristic of the aromatic crown ether, with a maximum at 343 nm. It is worth emphasizing that these results contrast with the usual behavior of chemical systems that either remain unchanged or undergo very different changes upon addition of reactants of opposite chemical nature such as amines and acids. An important consequence of this behavior is that the input/output relationships of the system correspond to those of the XOR (eXclusive OR) logic operation [56]. This development shows [26] that carefully designed dual-mode chemically driven molecular machines are potentially useful for information processing.

A somewhat related system is based on the electrochemically driven exchange of a guest between two hosts (see Section 6.5.3 and Figure 18). The mechanical movements taking place in such a system open the way to second-generation devices in which the electrochemically driven movements can control the selection of the partner in energy transfer or electron transfer processes [30]. Consider, for example a system (Figure 25) where a chromophoric group **A** is appended to the potential guest and chromophoric groups **B** and **C**, whose lowest excited states are lower than that of **A**, are appended to the potential hosts 4^{4+} and **2**, respectively. In such a system, light excitation of **A** could lead to no energy transfer (OFF), energy transfer to **B** (ON 1), or energy transfer to **C** (ON 2), depending on the potential value selected by the operator. Clearly, if energy transfer has to proceed through the

Figure 25. Schematic representation of the concept of a three-pole supramolecular switching of energy transfer. The association/dissociation processes are those shown in Figure 18; A, B, and C are suitably chosen photoactive groups. For more details, see text [30].

charge-transfer connections, there are severe limitations as to the choice of the chromophoric groups to be used. However, it does not seem unlikely that systems can be designed where molecular association either relies on a different kind of interaction (e.g., hydrogen bonding), or simply plays the role of bringing the two chromophoric groups at a suitable distance for through-space energy transfer. Similar switching of electron transfer processes could also be performed and more complex energy transfer and/or electron transfer patterns are conceivable. The strategy described above can also be used, in principle, to catalyze chemical reactions.

6.6.5 Sensors

As we have seen above, the formation of pseudorotaxanes in most cases is accompanied by noticeable changes in the spectroscopic and electrochemical properties. This feature can be exploited for sensory purposes [15, 68]. Changes in fluorescence are particularly useful in this regard because fluorescence spectroscopy is a simple and sensitive technique. Interestingly, an amplification of the fluorescence change signal can be obtained in appropriately designed systems. For example [68b,c], in a conjugated polymer with many appended fluorescent electron-donor macrocycles, the threading of an electron acceptor into one of the macrocycles can cause the

Figure 26. Schematic representation of a sensory signal amplification upon formation of a poly-pseudorotaxane from a conjugated polymer with appended many fluorescent electron-donor macrocycles. Threading only one macrocycle by an electron acceptor can cause the quenching, by energy or electron transfer, of the fluorescent excited state of remote macrocycles [68b].

quenching of several of them because of an intrastrand energy or electron migration (Figure 26).

6.6.6 Other Systems

An interesting case of a CT interaction triggered by a chemical input is exhibited by compound **34**⁺, which is made of a macrocycle containing electron-donor units, with appended a 4-pyridyl(4-pyridinium) tail [69]. In CH₂Cl₂ solution, **34**⁺ shows the well-known absorption bands of the component chromophoric groups, as well as the fluorescence band of the dioxynaphthalene unit. Addition of trifluoroacetic acid causes the appearance of the characteristic broad and weak CT band in the visible region ($\lambda_{\text{max}} = 510 \text{ nm}$, $\epsilon = 270 \text{ M}^{-1} \text{ cm}^{-1}$) and the disappearance of the dioxynaphthalene fluorescence band. This shows that, upon protonation of the pyridine unit, the tail becomes a strong electron acceptor which, therefore, threads the electron-donor macrocycle (Figure 27). Subsequent addition of tributylamine causes the disappearance of the CT absorption and the revival of the fluorescence, showing

Figure 27. Reversible threading/dethreading of compound **34**⁺ upon acid/base stimulation (CH₂Cl₂, 298 K) [69].

that the process is fully reversible. In MeCN, addition of acid does not cause the threading process since the protonated (dicationic) tail is strongly stabilized in polar solvents.

Compound 34^+ can be used in another interesting cyclic processes, as shown schematically in Figure 28 [69]. In CH_2Cl_2 solution, addition of the electron-acceptor wire-type *trans*-1,2-bis(1-benzyl-4-pyridinium)ethylene compound 35^{2+} causes a threading process with formation of the $[35 \cdot 34]^{3+}$ pseudorotaxane (Figure 28). Subsequent addition of trifluoroacetic acid causes the protonation of the pyridine unit of the tail of 34^+ . Since the protonated tail is a stronger electron acceptor than thread 35^{2+} , the latter is pushed out of the macrocycle, as indicated by changes in the absorption and emission spectra. The process is fully reversible by addition of tributylamine. In such a system, proton can close and amine can re-open the “door” of the macrocyclic cavity of 34^+ , thus preventing or allowing encapsulation of an external guest.

6.7 Heterogeneous Systems

The systems discussed above have been studied in solution, where each molecule behaves independently. Incoherence, therefore, remains a major impediment to designing and realizing systems capable of performing useful functions. The problem of obtaining ordered arrays of molecular devices that can communicate with the macroscopic world can be addressed by their aggregation on surfaces [70] or organization at liquid–gas or liquid–liquid interfaces [71].

For example, one can design systems like those illustrated in Figure 29 in which either the thread or the macrocycle is immobilized on an appropriate solid surface [72]. If the surface is an electrode [73], it may be possible to induce a coherent dethreading/rethreading movement under electrochemical control. By using a semiconductor surface, it may be possible to cause light-induced processes. An interesting approach is provided by the emerging field of heterosupramolecular chemistry, where molecular or supramolecular species are linked to nanoparticles [74].

6.8 Conclusions

Pseudorotaxanes represent a particular class of *complexes*—a term first used to describe Werner-type [75] metal complexes, also called coordination compounds. Complexes formed by organic molecules began to attract the attention of chemists around 1950, Mulliken in particular, in a landmark series of papers [76], formulated a theoretical treatment to explain the bonding characteristics and spectral properties of organic complexes based on charge-transfer interactions. During the past 20

Figure 28. The chemically driven processes occurring for the $34^+/35^{2+}$ system (CH_2Cl_2 , 298 K) [69].

Figure 29. Pseudorotaxanes formed by grafting (a) a thread or (b) a macrocycle on a surface.

years, it has become clear that both metal-based coordination compounds and organic charge-transfer complexes belong to the broader field of supramolecular chemistry, which includes any kind of species formed from the associations of cationic, anionic, and neutral molecular compounds [77].

Pseudorotaxanes based on charge-transfer interactions belong to the Mulliken-type complexes. Furthermore, they exhibit an organized structure somewhat similar to that of metal-based coordination compounds [33], [78]. Because of this combination of properties, pseudorotaxanes offer the opportunity to make use of electron transfer concepts and techniques along new directions. As we have seen above, electron transfer processes (performed by chemical, photochemical, or electrochemical stimulations) can be exploited to control threading/dethreading mechanical-like movements while, in their turn, mechanical-like movements (performed by chemical, photochemical, or electrochemical stimulations) can govern the occurrence of electron transfer processes or charge-transfer interactions. These concepts may be useful for the design of devices for information processing at the molecular level.

72. Another problem related to movements in supramolecular systems like pseudorotaxanes in solution is that of establishing which component is moving and which is not—a question that cannot even be addressed because of the lack of a fixed reference system. The problem, however, becomes addressable when in a [2]pseudorotaxane either the thread or the macrocycle is immobilized on a fixed frame such as a surface.

7 Electron Transfer Processes in Rotaxanes and Catenanes

Roberto Ballardini, Maria Teresa Gandolfi, and Vincenzo Balzani

7.1 Introduction

Rotaxanes [a name derived from the Latin words *rota* (wheel) and *axis* (axle)] [1] and *catenanes* [from the Latin word *catena* (chain)] [1] are supramolecular (multi-component) species [1–10] strictly related (Figure 1) to pseudorotaxanes, which were described in Volume III, Part 2, Chapter 6. Whereas pseudorotaxanes can undergo dissociation into their wire-like and macrocyclic components, rotaxanes and catenanes are interlocked species, whose dissociation requires breaking of a covalent bond. It should be pointed out, however, that, as discussed in detail in the previous chapter 6, the boundary between rotaxanes and pseudorotaxanes is somewhat “fuzzy” because, for example, when the stoppers are not extremely bulky compared to the hole of the macrocyclic component, a rotaxane at low temperature might well be a pseudorotaxane at elevated temperature [11].

Research on rotaxanes and catenanes has developed exponentially during the past few years [1–10]. Before discussing the electron transfer processes taking place in rotaxanes and catenanes, we will briefly recall the synthetic approaches to these fascinating compounds. The general way to indicate a rotaxane or a catenane is [n]rotaxane and [n]catenane, where n is the number of interlocked components.

7.2 Synthesis

Early attempts at the synthesis of catenanes were based on the so-called statistical approach. For example, according to this approach, a molecular thread X–Y, functionalized on both ends, may enter into a macrocycle of adequate size; subsequent cyclization of X–Y leads to two interlocked rings. Since the probability that cyclization occurs while X–Y is threaded through the macrocycle is very small, only poor yields can be expected.

Figure 1. Schematic representation of (a) [2]pseudo-rotaxanes, (b) [2]rotaxanes, and (c) [2]catenanes.

The first evidence for formation of a catenane following this approach was reported in 1960 [12], whereas the first synthesis of a rotaxane was reported in 1967 [13]. In the same year it was discovered that catenanes are also formed in nature by DNA [14, 15]. From a preparative viewpoint, statistical threading became significant in 1976, when a threading process that probably involves a weak molecular recognition between the thread and the macrocycle was used [16]. Alternative methods used to obtain catenanes were the Möbius strip approach [17], which is again statistical in nature, and the direct synthesis about a central core [18, 19], which is successful but requires a great deal of technical expertise and manipulation. With the development of the host–guest chemistry in the late 1970s [20, 21], several research groups began to develop new methods for synthesizing rotaxanes and catenanes.

The general strategy to prepare rotaxanes and catenanes with high yields is based on the template effect [22], which relies on the presence of molecular recognition sites between the components to be assembled. The most common templated syntheses involve the use of metal ions [4], donor–acceptor components [3, 5, 8], and the formation of hydrogen bonds [5, 6]. However, other properties, such as hydrophobic–hydrophylic character, π – π stacking, ion–ion, ion–dipole, and dipole–dipole forces can also play a role. In several cases, in fact, more than one type of interaction is operative. It should also be noted that in some cases the strongest interaction, as far as association is concerned, is not that causing the most relevant changes (compared to the separated components) in properties such as electrochemical behavior and absorption, fluorescence, and NMR spectra.

Figure 2 shows the routes by which components bearing suitable recognition sites lead to the formation of rotaxanes: (i) *threading* a molecule through a preformed ring followed by capping the end of the thread; (ii) *slipping* a preformed ring over the stoppers of a preformed dumbbell-shaped into a thermodynamically favorable site on the rod part of the dumbbell; and (iii) *clipping* a macrocycle onto a preformed dumbbell.

Figure 2. Routes for the synthesis of [2]rotaxanes.

Figure 3 shows the synthesis of the [2]rotaxane 3^{4+} by the threading or the clipping approach [23]. In the first case (Figure 3a), threading of the electron-acceptor tetracationic cyclophane 1^{4+} by the thread **2**, which contains a hydroquinone electron-donating unit, yields a pseudorotaxane; then, reaction of the terminal hydroxy groups of the thread with triisopropylsilyl triflate leads to the [2]rotaxane 3^{4+} . In the clipping approach (Figure 3b), the [2]rotaxane is obtained from the reaction of the dication 4^{2+} with dibromide **5** in the presence of the preformed dumbbell-shaped component **6**. Figure 4 shows the preparation of a [3]rotaxane by riveting two rings together, taking advantage from the hydrogen-bond driven preformation of a pseudorotaxane structure [24].

Figure 3. Synthesis of a [2]rotaxane by the (a) threading and (b) clipping approaches [23].

In the case of catenanes, the most rationale preparation strategy is clipping of a preformed macrocycle with a suitable U-type component that is subsequently cyclized. A double clipping procedure can also be used (Figure 5) [5].

Figure 6 shows the synthesis, templated by donor–acceptor and hydrogen-bonding interactions, of [2]catenane **8**⁴⁺ [23]. Reaction of the dication **4**²⁺ with the

Figure 4. Synthesis of a [3]rotaxane by riveting two rings together [24].

Figure 5. Routes for the synthesis of [2]catenanes.

Figure 6. Synthesis of a [2]catenane templated by donor–acceptor and hydrogen bond interactions [23].

dibromide **5** gives a tricationic intermediate which interacts with bis(*p*-phenylene)-34-crown-10 (**7**) to afford a pseudorotaxane-like, or precatenane, structure. The subsequent macrocyclization, as a result of nucleophilic displacement of bromide ion, gives the corresponding [2]catenane 8^{4+} .

In some cases, catenanes are formed from relatively small molecules by one-pot synthesis in a more or less serendipitous manner [25]. Figure 7 shows the one-pot synthesis of the amide-based [2]catenane **9** from very simple compounds [25c]; this synthesis is thought to involve the perpendicular preorganization of the components caused by three templating effects: (i) steric complementarity; (ii) hydrogen bonding between carbonyl oxygen atoms and amide protons; and (iii) π - π interactions between the benzene rings of host and guest units.

Besides simple rotaxanes and catenanes, a great variety of more complex systems have been synthesized, including: branched [n]rotaxanes [26a], [n]rotaxanes bearing dendritic stoppers [26b], catenanes composed by two, three, five, or seven interlocked macrocycles [26c,e], polyrotaxanes and polycatenanes [2–6, 8], catenanes with very special shapes [27], rotocatenanes [28], pretzelanes [29], and knots [4]. Some of these compounds are shown in Figure 8.

Figure 7. One-pot synthesis of an amide-based [2]catenane. Besides the catenane, macrocycles are also formed [25c].

Figure 8. Examples of rotaxanes and catenanes with peculiar structures. (a) A branched [4]rotaxane [26a]; (b) a [5]catenane (olympiadane) [26c]; (c) a rotocatenane [28]; (d) a [2]catenane with three rings [27d].

7.3 Spectroscopic and Electrochemical Consequences of Charge–Transfer Interactions

As in the case of pseudorotaxanes (see Volume III, Part 2, Chapter 6), charge–transfer (CT) interactions between electron-donor and electron-acceptor units in rotaxanes and catenanes have several important consequences from the spectro-

Figure 9. Absorption spectrum in MeCN at 25 °C of (a) a 4.0×10^{-5} M solution of catenane 8^{4+} and (b) equimolar amounts of its separated components (cyclophane 1^{4+} and macrocycle **7**) [23].

scopic and electrochemical viewpoints [23] and play a fundamental role as far as the machine-like behavior of these compounds is concerned [30–33].

7.3.1 Absorption and Emission Spectra

The donor–acceptor interaction introduces low-energy CT excited states which are responsible for the presence of broad and relatively weak (ϵ of the order of 10^2 – 10^3 $\text{M}^{-1} \text{cm}^{-1}$) bands in the visible spectral region. For example, [2]catenane 8^{4+} shows a broad absorption band, with maximum at 470 nm ($\epsilon = 700 \text{ M}^{-1} \text{cm}^{-1}$), which is not present in the spectra of the separated components (Figure 9) [23]. As expected, the position of the CT bands moves towards higher energies with increasing ionization potential of the donor and decreasing electronic affinity of the acceptor. When different electron-donor and/or electron-acceptor units are present in the same compound, the CT absorption region is very broad because of the contribution of CT transitions at different energies [34]. This is also the case of catenanes made of symmetric rings, like 8^{4+} , because the two identical electron-donor (or -acceptor) units present in the separated components occupy topologically different (“alongside” and “inside”) positions in the catenane and, therefore, they are no longer equivalent. Besides the absorption bands arising from CT interactions, bands due to transitions substantially localized in the component species are of course present in the absorption spectra of rotaxanes and catenanes. These bands are more or less perturbed (particularly in intensity) compared to the bands exhibited by the separated components (see, e.g., Figure 9).

The CT excited states usually are not emissive because the low energy gap and the strong distortion with respect to the ground state favor the occurrence of radiationless deactivation. Furthermore, the presence of the low-energy CT excited states causes rapid radiationless decay of the upper lying, potentially luminescent excited states localized on the molecular components. Therefore, rotaxanes and catenanes based on CT interactions usually do not exhibit any luminescence. For example, the intense emission band with maximum at 320 nm ($\tau = 2.5$ ns) exhibited by macrocycle **7** [11a] is no longer present in catenane **8**⁴⁺ [23].

7.3.2 Electrochemical Behavior

As far as the electrochemical behavior is concerned, it should be recalled that, when engaged in CT interactions, the electron-donor and electron-acceptor units become more difficult to oxidize and to reduce, respectively (see Volume III, Part 2, Chapter 6). Furthermore, as mentioned above, units which are topologically equivalent in an isolated component become nonequivalent when the component is engaged in nonsymmetric interactions with another component. Consider, for example, the case of [2]rotaxane **3**⁴⁺ and [2]catenane **8**⁴⁺, in which one of the two components is cyclophane **1**⁴⁺ (Figure 10) [23]. Such a cyclophane, which comprises two equivalent, noninteracting, bipyridinium electron-acceptor units, shows two bielectronic reduction processes, the first one corresponding to the uptake of the first electron by each of the equivalent bipyridinium units, and the second one to the subsequent reduction of the monoreduced units to give neutral species [23, 35]. In rotaxane **3**⁴⁺, cyclophane **1**⁴⁺ is threaded by the dumbbell component **6**, which contains an electron-donor unit. As a consequence of the CT interaction, the half-wave potentials associated with the first and second reduction processes of the bipyridinium units are shifted to more negative values. In the rotaxane structure, the two bipyridinium units are still equivalent because they experience an equal amount of electron donation and therefore are reduced at the same potential. A CT interaction is present also in catenane **8**⁴⁺, since the macrocycle **7** contains electron-donor units. Therefore, the reduction potentials of the bipyridinium units of the cyclophane move again towards more negative potentials (Figure 10). In the catenane structure, however, the two bipyridinium units occupy topologically different (“alongside” and “inside”) positions. The unit which is inside the macrocycle **7** experiences a stronger CT interaction than the unit which is alongside. Therefore, the first two-electron reduction process splits into two distinct one-electron processes. When both the bipyridinium units have been monoreduced, the CT interaction with the electron-donor units of macrocycle **7** becomes very weak, so that the second reduction process does not split. In some cases, splitting of the second two-electron reduction process can also be observed [36]. The above discussion, which refers to the reduction of the electron-acceptor components, can be extended to the oxidation of the electron-donor components [23, 26e, 36, 37].

As an example of more complex systems, we now consider the electrochemical behavior of macrocycle **10**, which contains three electron-donor dioxynaphthalene units, and [2]catenane **11**⁴⁺ and [3]catenane **12**⁸⁺ in which macrocycle **10** is inter-

Figure 10. Correlation diagram for the electrochemical reduction of cyclophane 1^{4+} , [2]rotaxane 3^{4+} , and [2]catenane 8^{4+} (MeCN, 25 °C, potentials versus SCE); bielectronic processes are indicated [23].

locked with cyclophane **1**⁴⁺ as an electron acceptor component [26c]. Figure 11 shows the correlation diagram for the redox processes observed in these compounds. In the catenanes, the two bipyridinium units of cyclophane **1**⁴⁺ are engaged in donor–acceptor interactions and occupy spatially different sites, as discussed above. Therefore, it can again be expected that their reduction takes place in separated processes at more negative potentials compared to free **1**⁴⁺. This is clearly the case for the first reduction of the two bipyridinium units in the [2]catenane **11**⁴⁺: the alongside unit is reduced at –0.36 V, and the inside one at –0.47 V versus SCE. Comparison with the [2]catenane composed of **1**⁴⁺ and 1,5-dinaphtho-38-crown10 (a macrocycle like **10**, but containing only two donor units) [36a] shows that in **11**⁴⁺ the first reduction process is practically unaffected by changing the macrocycle, whereas the second one is considerably displaced towards less negative potentials. This difference could result from the greater size and flexibility of macrocycle **10** which allow one of the donor units to interact with the alongside bipyridinium unit of the cyclophane and, at the same time do not force two donor units to sandwich the inside bipyridinium unit. After the first reduction, the electron donor–acceptor interaction becomes weaker, and the flexible nature of the **10** could facilitate a rapid interchange between monoreduced inside and alongside units, with a consequent lack of splitting of the second process. For [3]catenane **12**⁸⁺, composed of **10** and two equivalent **1**⁴⁺ cyclophanes, simultaneous reduction of the alongside units of the two cyclophanes is followed by simultaneous reduction of the inside units. Both processes are displaced to less negative potentials compared to **11**⁴⁺ because the ratio between electron-donor and electron-acceptor units decreases from 3/2 to 3/4, and the positive charge increases. The splitting of the second reduction process of the bipyridinium units is consistent with the crowded structure of the catenane which presumably prevents rapid interchange between inside and alongside units.

In macrocycle **10**, the three donor units undergo distinct oxidation processes, indicating that there are electronic interactions between oxidized and nonoxidized units. As a consequence of the CT interaction with the electron-acceptor cyclophane, in the catenane **11**⁴⁺ all these processes move to more positive potential values with respect to the free macrocycle. A detailed comparison between the two oxidation patterns is made difficult because, in the catenane structure, the donor–acceptor interactions between nonoxidized and oxidized donor units are partially or completely prevented. In the [3]catenane **12**⁸⁺, only two oxidation processes are observed, a feature which is consistent with the presence of an outside and two equivalent inside donor units.

7.4 Rotaxanes

7.4.1 Rotaxane Chemistry

Because of their *wheel* and *axle* structure, much of the interest in rotaxane chemistry is focused on the mechanical movements of the ring around and along the dumbbell-shaped component. Of particularly interest is the possibility to control

Figure 11. Correlation diagram for the electrochemical behavior of [2]catenane **11**⁴⁺, [3]catenane **12**⁸⁺, and their **1**⁴⁺ and **10** components (MeCN solution, 25 °C, potentials versus SCE); bielectronic processes are indicated [26c].

such movements by external stimuli which modify the electronic interactions between the wheel and axle components. This topic will be discussed in detail below. There are, however, other interesting aspects of rotaxane chemistry. For example, it has been shown that the wheels can be used as noncovalent protecting groups towards functional groups contained in the axle [38].

7.4.2 Shuttling Processes

It is possible to synthesize [2]rotaxanes containing two identical recognition sites within their dumbbell component. The result is a degenerate equilibrium state in which the macrocyclic component can shuttle back and forth along the linear portion of the dumbbell. Such a system constitutes a *molecular shuttle*. Two examples [11a,b, 39] of [2]rotaxanes that behave as degenerate molecular shuttles are shown in Figure 12.

Figure 12. Shuttling of a ring between two equivalent stations in a [2]rotaxane. (a) The bipyridinium-based cyclophane shuttles from one 1,4-dioxymethylene recognition site to the other at a rate of c. 2000 s^{-1} in $(\text{CD}_3)_2\text{CO}$ at ambient temperature [39a,b]. (b) The 1,4-dioxymethylene-based macrocyclic polyether shuttles from one bipyridinium recognition site to the other one at a rate of c. $3 \times 10^5\text{ s}^{-1}$ under the same conditions [39c].

Figure 13. The two spatial arrangements (co-conformations) associated with a [2]rotaxane, incorporating two different recognition sites within its dumbbell-shaped component, can be interchanged by appropriate stimuli.

When the two recognition sites in the dumbbell-shaped component differ in their constitutions, the [2]rotaxane can exist as two different, equilibrating, three-dimensional spatial arrangements (co-conformations [40]) whose populations reflect their relative free energies as determined primarily by the strengths of the two different sets of noncovalent bonding interactions. In the schematic representation shown in Figure 13, it has been assumed that the molecular shuttle resides preferentially in 'state 0' until a stimulus is applied that switches off the stronger of the two recognition sites, thus inducing the macrocycle to move to the second weaker recognition site ('state 1'). In appropriately designed [2]rotaxanes, this nondegenerate process can be controlled reversibly using stimuli that are either chemical, electrochemical, or photochemical [30–33, 41]. The most common useful processes to alter reversibly the stereoelectronic properties of one of the two recognition sites are protonation/deprotonation and oxidation/reduction processes, but solvent-induced co-conformational changes have also been extensively investigated [42]. By switching off and on the recognition properties of one of the two recognition sites, the relative proportions of the two species can be controlled reversibly. Such compounds exhibit an abacus-like geometry and behave according to binary logic. Therefore, they could be used, in principle, for information processing at the molecular level.

7.4.3 Electrochemically Controlled Shuttling Processes

Figure 14 shows [2]rotaxane **13**⁴⁺ which contains two recognition sites in its dumbbell-shaped component. In this compound, the stable structure is that with the macrocyclic component surrounding the benzidine recognition site, but shuttling of the macrocycle between the two sites can be controlled electrochemically [43]. The

Figure 14. Shuttling of the macrocyclic component of [2]rotaxane 13^{4+} along its dumbbell-shaped component can be controlled electrochemically by oxidizing/reducing the benzidine unit [43]. Shuttling of the macrocycle component can also be controlled by protonating/deprotonating the benzidine unit (see text).

benzidine site undergoes two consecutive one-electron oxidations. Comparison of the half-wave potentials of the [2]rotaxane with those of a model compound incorporating a benzidine unit not encircled by the tetracationic cyclophane shows that the potential for the first oxidation is more positive in the [2]rotaxane, while that for the second oxidation is the same in both compounds. These observations indicate that the tetracationic cyclophane 1^{4+} makes the first one-electron oxidation of the encircled benzidine unit more difficult. However, once this unit is oxidized to the corresponding radical cation, the tetracationic cyclophane moves away from it to encircle the biphenol unit, and so does not influence the second one-electron oxidation. Upon reduction of the benzidine unit back to its neutral state, the original equilibrium between the two co-conformations associated with the [2]rotaxane is restored. The shuttling of the macrocycle component in 13^{4+} can also be controlled by protonation/deprotonation [43].

Figure 15. Shuttling of the macrocyclic component of 14^{4+} along its dumbbell-shaped component can be induced by oxidizing electrochemically the anthracene unit system [44].

The [2]rotaxane 14^{4+} incorporates a π -electron-deficient macrocycle and a π -electron-rich dumbbell (Figure 15) [44]. ^1H NMR studies demonstrated that, in solution, the macrocycle resides around the 2,6-dioxyanthracene recognition site. This arrangement is stabilized by π - π stacking interactions between the bipyridium units of the macrocycle and the sandwiched 2,6-dioxyanthracene recognition site of the dumbbell, as well as by $[\text{C}-\text{H}\cdots\text{O}]$ interactions between the α -bipyridinium hydrogen atoms and the polyether oxygen atoms. The cyclic voltammogram of a MeCN solution of this [2]rotaxane shows a first oxidation wave (+1.03 V versus SCE) that corresponds to the oxidation of the 2,6-dioxyanthracene recognition site. This oxidation occurs at a potential that is more positive than that of a model compound incorporating this unit. As far as the oxidation of the two 1,4-dioxybenzene units is concerned, two waves (+1.29 and +1.59 V versus SCE) are observed. The oxidation of the first 1,4-dioxybenzene unit of the [2]rotaxane occurs at a potential that is almost identical to that of a model compound incorporating this unit. The

oxidation of the second 1,4-dioxybenzene unit occurs at a potential that is almost identical to that of a model [2]rotaxane incorporating this unit encircled by the tetracationic cyclophane. These observations suggest that the tetracationic cyclophane resides initially around the 2,6-dioxyanthracene recognition site (Figure 15), making its oxidation more difficult. However, once this recognition site is oxidized, the tetracationic cyclophane moves away from it and encircles one of the two 1,4-dioxybenzene units.

Electrochemically induced shuttling has also been obtained [45] in [2]rotaxanes based on Cu^+ , as described in detail in Volume III, Part 2, Chapter 8.

7.4.4 Photochemically Controlled Shuttling Processes

In the rotaxanes based on electron donor–acceptor interactions there are low-energy CT excited states which are responsible for the absorption bands observed in the visible region (see, e.g., Figure 9). Light excitation in these CT absorption bands formally leads to the transfer of an electron from an electron-donor to an electron-acceptor unit (optical electron transfer). As a consequence, one can expect destabilization of the original rotaxane structure, followed by a displacement of the ring along the wire (in pseudorotaxanes, such a destabilization is expected to lead to dethreading; see Volume III, Part 2, Chapter 6). In practice, however, this simple approach to obtain a photoinduced motion of the ring is not likely to be successful, because the back electron transfer process is much faster than the extended nuclear motions and solvent rearrangement needed for moving the ring. An attempt along this direction has been performed on the rotaxane $\mathbf{15}^{4+}$ shown in Figure 16 [46]. Direct excitation into the CT absorption band results in the transfer of an electron from the central dioxybenzene donor to the cyclophane acceptor. Rapid ($\tau = 30$ ps) back electron transfer occurs, in competition with a minor process involving hole transfer to a ferrocene stopper. The latter process creates a longer-lived ($\tau = 555$ ns) excited state, but back electron transfer to form the initial ground state is still much faster than the motion of the ring.

In order to achieve photoinduced shuttling, the carefully designed [2]rotaxane $\mathbf{16}^{6+}$ shown in Figure 17 has been recently synthesized [47]. This compound is made of the electron-donor macrocycle **R**, and a dumbbell-shaped component which contains: (i) a photoactive Ru(II) polypyridine complex (**P**) as one of its stoppers; (ii) a 4,4'-bipyridinium unit (**A**₁) and a 3,3'-dimethyl-4,4'-bipyridinium unit (**A**₂) as electron accepting stations; (iii) a *p*-terphenyl-type ring system as a rigid spacer (**S**); and (iv) a tetraarylmethane group as the second stopper (**T**). The structure of [2]rotaxane $\mathbf{16}^{6+}$ was characterized by mass spectrometry and NMR spectroscopy, which also established, along with cyclic voltammetry, that the stable translational isomer is the one in which the **R** component encircles the **A**₁ unit, in keeping with the fact that this station is a better electron acceptor than the other one. The electrochemical, photophysical, and photochemical (under continuous and pulsed excitation) properties of the [2]rotaxane, its dumbbell-shaped component, and some model compounds containing electro- and photoactive units (Figure 17), have been investigated. In an attempt to obtain the photoinduced abacus-like movement of the

Figure 16. Optical electron transfer excitation of [2]rotaxane 15^{4+} [46]. Shuttling does not take place because the direct and ferrocene-mediated back electron transfer reactions are much faster than the motion of the ring.

R macrocycle between the two stations A_1 and A_2 , two strategies have been devised: one was fully based on processes involving only the rotaxane components (intramolecular mechanism), while the other one required the help of external reactants (sacrificial mechanism).

The intramolecular mechanism, illustrated in Figure 18, is based on the following four operations [47]:

- (a) *Destabilization of the stable translational isomer.* Light excitation of the photo-active unit **P** (Step ①) should be followed by the transfer of an electron from the excited state to the A_1 station, which is encircled by the ring **R** (Step ②), in order to “deactivate” this station: such a photoinduced electron transfer process has to compete with the intrinsic excited-state decay (Step ③).
- (b) *Ring displacement.* The ring should move from the reduced station A_1^- to A_2

Figure 17. The [2]rotaxane 16^{6+} designed to achieve an abacus-type behavior under light excitation [47].

(Step 4), a step that has to compete with the back electron transfer process from A_1^- (still encircled by **R**) to the oxidized photoactive unit P^+ (Step 5). This is the most difficult requirement to meet in the intramolecular mechanism.

- (c) *Electronic reset.* A back electron transfer process from the “free” reduced station A_1^- to P^+ should take place (Step 6), with consequent restoration of the electron-acceptor power to the A_1 station.

Figure 18. Intramolecular mechanism for the light-driven switching of the ring **R** between the two stations **A₁** and **A₂**. The dashed lines indicate processes that compete with those needed to perform shuttling [47].

(d) *Nuclear reset.* As a consequence of the electronic reset, back movement of the ring from **A₂** to **A₁** should occur (Step ⑦).

The most important requirement to meet in the intramolecular mechanism is the successful competition of Step ④ (which involves complex nuclear movements) with Step ⑤ (which only involves the transfer of an electron).

The alternative, less-demanding, sacrificial mechanism is based on the use of external redox reactants that operate after the photoinduced deactivation of the **A₁** station, as illustrated in Figure 19. This involves [47]:

- (a) *Destabilization of the stable translational isomer*, as in the previous mechanism.
- (b') *Ring displacement after scavenging of the oxidized photoactive unit.* If the solution contains a suitable reductant **Red**, a fast reaction of **Red** with **P⁺** (Step ⑧)

Figure 19. Sacrificial mechanism for the light-driven switching of the ring **R** between the two stations **A₁** and **A₂**. The dashed lines indicate processes that compete with those needed to perform shuttling [47].

may compete successfully with the back electron transfer reaction (Step ⑤); in such a case, the displacement of the ring to **A₂** (Step ④), even if it is slow, can take place because the originally occupied station remains in its reduced state **A₁⁻**.

(c') *Electronic reset.* After an appropriate time, restoration of the electron-acceptor power of the **A₁** station can be obtained by oxidizing **A₁⁻** with a suitable oxidant **Ox** (Step ⑨).

(d) *Nuclear reset*, as in the previous mechanism (Step ⑦).

The results obtained have shown that electronic reset of the system after light excitation (Step ⑤ in Figure 18) occurs with rate constant $8.3 \times 10^5 \text{ s}^{-1}$, which is likely comparable to that of the ring displacement (Step ④) [39c]. While clear evi-

dence for the intramolecular mechanism could not be obtained, the photochemically driven switching was successfully performed by the sacrificial mechanism (Figure 19) with triethanolamine as **Red** and dioxygen as **Ox** [47]. Of course, the intramolecular switching mechanism (Figure 18) is much more appealing than the sacrificial one, principally because the former mechanism implies the conversion of light energy into mechanical energy without using other chemicals and without generation of waste products.

A photochemically induced ring movement has been obtained in a [2]rotaxane based on Cu^+ [45], as described in detail in Volume III, Part 2, Chapter 8. Shuttling of a α -cyclodextrin torus along an azobiphenoxy-containing dumbbell has also been obtained by exploiting the *trans/cis* photoisomerization of the azobiphenoxy unit [48].

Figure 20. Ring motions in [2]rotaxane 17H^{3+} upon deprotonation/protonation [49].

7.4.5 Chemically Controlled Shuttling Processes

No example has so far been reported of a shuttling process controlled by electron transfer chemical reactions. There are, however, very interesting examples of shuttling processes controlled by acid/base reactions. One case is that of the previously discussed compound **13**⁴⁺ (see Figure 14), in which the shuttling of the macrocycle component can be controlled not only electrochemically, but also by protonation/deprotonation of the benzidine unit [43].

Another very interesting case of shuttling controlled by acid/base reactions is that of [2]rotaxane **17H**³⁺, which incorporates a dialkylammonium and a bipyridinium recognition site in its dumbbell-shaped component (Figure 20) [49]. The macrocycle resides exclusively around the ammonium recognition site as a result of a combination of [⁺N–H···O] and [C–H···O] interactions between the [CH₂NH₂⁺] hydrogen atoms of the dumbbell and the oxygen atoms of the macrocycle. Upon addition of an excess of a suitable amine to a solution of this [2]rotaxane, deprotonation of the ammonium recognition site occurs. As a result, the intercomponent hydrogen bonds are destroyed and the macrocycle moves to the bipyridinium recognition site. However, the original structure is restored after the addition of a suitable acid, since the protonation of the ammonium recognition site is followed by the return of the macrocycle back to encircle the [NH₂⁺] center. The shuttling process can be followed by ¹H NMR spectroscopy (in (CD₃)₂CO) and by electrochemical techniques (in MeCN) [49].

Rotaxanes changing shape through switchable thread–macrocycle interactions have also been reported [50].

7.5 Catenanes

7.5.1 Functional Catenanes

Since the synthetic methods to obtain catenanes have been well established, increasing attention is devoted to the incorporation of novel functions in these structures. Of particular interest are the catenanes in which either the electron-acceptor cyclophane ring or the electron-donor macrocycle contain a 2,2'-bipyridine ligand. Starting from the **L**₁⁴⁺ cyclophane ligand (Figure 21), the mononuclear [Re(CO)₃Cl**L**₁]⁴⁺, [Ru(bpy)₂**L**₁]⁶⁺, [Ag(**L**₁)₂]⁹⁺, and [Cu(**L**₁)₂]⁹⁺ complexes have been prepared [51]. From the bis-chelating cyclophane ligand **L**₂⁴⁺, the dinuclear complexes [{Re(CO)₃Cl}₂**L**₂]⁴⁺ and [{Ru(bpy)₂}₂**L**₂]⁸⁺ have also been obtained (Figure 22) [51].

In the case of **L**₂⁴⁺ it was not possible to synthesize [2]catenanes because the cavity of this cyclophane is too large to give stable complexes with aromatic crown ethers in the templated synthetic approach. Starting from **L**₁⁴⁺, however, it was possible to prepare the [2]catenane ligands **L**₃⁴⁺ and **L**₄⁴⁺ which were then used to prepare several mononuclear [2]catenane complexes (Figure 23). These compounds were characterized by NMR spectroscopy, mass spectrometry and, in some cases, X-ray crystallography.

Figure 21. Preparation of mononuclear complexes of the cyclophane ligand L_1^{4+} [51].

The absorption spectra, luminescence properties, and electrochemical behavior of the L_1^{4+} , L_2^{4+} , and L_4^{4+} ligands, and of the $[\text{Re}(\text{CO})_3\text{Cl}L_1]^{4+}$, $[\text{Re}(\text{CO})_3\text{Cl}L_4]^{4+}$, $[\{\text{Re}(\text{CO})_3\text{Cl}\}_2L_2]^{4+}$, $[\text{Ru}(\text{bpy})_2L_1]^{6+}$, $[\text{Ru}(\text{bpy})_2L_4]^{6+}$, and $[\{\text{Ru}(\text{bpy})_2\}_2L_2]^{8+}$ complexes have then been investigated [51]. Besides the ligand-centered bands, the Re(I) and Ru(II) complexes display metal-to-ligand charge-transfer (MLCT) bands in the visible region similar to those of the $\text{Re}(\text{CO})_3(\text{Cl})(\text{bpy})$ and $[\text{Ru}(\text{bpy})_3]^{2+}$ model compounds. None of the examined complexes exhibits emission at room temperature because the potentially luminescent MLCT excited state undergoes electron transfer quenching by the bipyridinium-type units contained in the L_1^{4+} , L_2^{4+} , and L_4^{4+} ligands. In rigid matrix at 77 K, where electron transfer cannot occur, emission can be observed from the complexes containing the tetracationic cyclophane ligands L_1^{4+} and L_2^{4+} , but not from those containing the catenane ligand L_4^{4+} , in which quenching can still take place by energy transfer to a low-energy CT excited state of the catenane moiety [51].

In the potential window examined ($-2.2/+2.1$ V versus SCE), L_1^{4+} and L_2^{4+} can reversibly accept five and, respectively, six electrons, with processes localized on their bipyridinium- and bpy-type units. The catenane ligand L_4^{4+} , besides the re-

Figure 22. Preparation of binuclear complexes of the cyclophane ligand L_2^{4+} [51].

duction processes concerning the L_1^{4+} cyclophane, displays two oxidation processes involving the dioxynaphthalene moieties of the 1,5-dinaphtho-38-crown-10. The $[Re(CO)_3L_1Cl]^{4+}$, $[Re(CO)_3L_4Cl]^{4+}$, $[\{Re(CO)_3Cl\}_2L_2]^{4+}$, $[Ru(bpy)_2L_1]^{6+}$, $[Ru(bpy)_2L_4]^{6+}$, and $[\{Ru(bpy)_2\}_2L_2]^{8+}$ complexes display several redox processes (up to a total of 10 exchanged electrons in the case of $[Ru(bpy)_2L_4]^{6+}$ and $[\{Ru(bpy)_2\}_2L_2]^{8+}$) that can be assigned to: (i) reduction of the bipyridinium- and bpy-type moieties of the catenane ligands; (ii) reduction of the bpy ligands (in the Ru complexes); (iii) oxidation of the metals; and (iv) oxidation of the dioxynaphthalene moieties of the 1,5-dinaphtho-38-crown-10 (in the complexes containing the

Figure 23. Preparation of mononuclear complexes of the catenane ligands L_3^{4+} and L_4^{4+} [51].

Figure 24. Cyclic voltammetric behavior on reduction of $5 \times 10^{-4} \text{ M } [Ru(bpy)_2L_4]^{6+}$ (MeCN, 25°C) [51].

L_4^{4+} catenane ligand). The cyclic voltammetric behavior on reduction of $[\text{Ru}(\text{bpy})_2\text{L}_4]^{6+}$ is shown in Figure 24: two monoelectronic waves and a bielectronic wave, assigned to the first and second reductions of the bipyridinium units, are followed by three monoelectronic waves involving reduction of the bipyridine moieties [51].

An interesting aspect of the above-described metal catenanes is the topologically different (“alongside” and “inside”) positions of the two bipyridinium units with respect to the crown ether (Figure 23) and, as a consequence, their redox asymmetry (Figure 24). Such a situation is reminiscent of the redox asymmetry present in the two branches of the reaction center of bacterial photosynthesis [52]. The photochemical behavior of [2]catenane $[\text{Ru}(\text{bpy})_2\text{L}_3]^{6+}$ has therefore been investigated by picosecond laser spectroscopy [53]. The excited state of the Ru moiety transfers an electron to the tetracationic cyclophane with rate constant $5.9 \times 10^{10} \text{ s}^{-1}$, and the back electron transfer restoring the ground state occurs with rate constant $2.4 \times 10^{10} \text{ s}^{-1}$. Unfortunately, no conclusion could be drawn as to the electron transfer path, since the two bipyridinium units cannot be distinguished by spectroscopic means.

As mentioned above, a coordinating bipyridine unit can also be incorporated in the electron-donor macrocycle of a catenane. This strategy has been followed to prepare the L_5^{4+} ligand and its $[\text{Ru}(\text{Me}_2\text{bpy})_2\text{L}_5]^{6+}$ complex (Figure 25) [54]. Electrochemical and dynamic ^1H NMR experiments, as well as molecular modeling, suggested that there are two conformers. Luminescence quenching data indicated that the rate of the electron transfer reaction from the excited state of the Ru moiety to the bipyridinium units of the cyclophane is $\geq 1 \times 10^8 \text{ s}^{-1}$ in water and that, apparently, there are two different back electron transfer processes of rate constants 4.1×10^6 and $1.9 \times 10^6 \text{ s}^{-1}$, assigned to two different conformers [54]. The $[\text{Ru}(\text{Me}_2\text{bpy})_2\text{L}_5]^{6+}$ catenane has recently been used as a component of a triad and incorporated into a protein scaffold [55].

Other interesting units that have been incorporated in the electron-donor macrocyclic component of catenanes are porphyrins (Figure 26) [56]. The compounds containing a free-base porphyrins can be protonated in strongly acidic solutions, causing electrostatic repulsions which result in conformational reorientations and changes in rotation rates [57].

Several [2]catenanes incorporating a calix[4]arene unit in their electron-acceptor cyclophane components have also been prepared (see, e.g., Figure 27) [58]. In these compounds, the characteristic charge-transfer bands arising from the donor-acceptor interaction are present, but no luminescence can be observed.

7.5.2 Ring Motions

When the synthesis of a [2]catenane leads to the interlocking of two different macrocycles each containing two identical recognition sites, then circumrotation of a macrocycle through the cavity of the other leads to degenerate equilibrium states. An example of a degenerate [2]catenane is shown in Figure 28, wherein the dynamic processes in solution are illustrated [23].

Figure 25. Macrocyclic ligand L_5 , its [2]catenane derivative L_5^{4+} , and the $[\text{Ru}(\text{Me}_2\text{bpy})_2\text{L}_5]^{6+}$ [2]catenane complex [54].

When one of the two macrocycles carries two different recognition sites, then the opportunity exists to control the dynamic processes in these switchable [2]catenanes in a manner reminiscent of the controllable molecular shuttles (Figure 29) [30–34, 41]. In essence, the requirement for being able to switch between ‘state 0’ and ‘state 1’ in such a [2]catenane is that the symmetric macrocyclic component resides preferentially around one of the two different recognition sites incorporated within the non-

Figure 26. Porphyrin [2]catenanes and possible structural changes accompanying diprotonation of the porphyrin ring [57].

Figure 28. Dynamic processes associated with [2]catenane 8^{4+} in solution, which involve the circumrotations of the macrocyclic components through each other's cavities [23].

Figure 29. The two spatial arrangements associated with a [2]catenane, incorporating two different recognition sites within one of its two macrocyclic components, can be interchanged by appropriate stimuli.

symmetric macrocycle. The two associated spatial arrangements (co-conformations) [40] are stabilized by intercomponent noncovalent bonding interactions, and their interconversion requires the circumrotation of the nonsymmetric macrocycle through the cavity of the symmetric one. In solution, the equilibrium between the two spatial arrangements is governed by the relative magnitudes of the intercomponent noncovalent bonding interactions. By switching off and on again the recognition properties of one of the two recognition sites of the nonsymmetric macrocycle, the relative populations of the two spatial arrangements can be controlled reversibly.

Complexation/decomplexation of metal ions or of neutral organic molecules, protonation/deprotonation reactions, and oxidation/reduction processes can all be exploited to alter reversibly the stereoelectronic properties of one of the two recognition sites, thus affecting its ability to sustain noncovalent bonds [30–34, 41]. These kinds of switchable [2]catenanes can be prepared following the template-directed synthetic strategy illustrated in Figure 5, wherein one of the two macrocyclic components is preformed and then the other one is clipped around it with the help of noncovalent bonding interactions.

7.5.3 Electrochemically Controlled Ring Motions

In the [2]catenane **18**⁴⁺ (Figure 30) the ring motion can be controlled electrochemically by oxidizing/reducing reversibly the tetrathiafulvalene unit [59]. The cyclic voltammogram of the ‘free’ macrocyclic polyether shows a reversible wave (c. +0.3 V versus SCE, MeCN) for the monoelectronic oxidation of the tetrathiafulvalene (TTF) unit. In the [2]catenane, the TTF unit is located inside the cavity of the tetracationic cyclophane, and its monoelectronic oxidation occurs at more positive potentials. Furthermore, a large separation between the anodic and cathodic peaks associated with this process is observed. This separation varies as the scan rate is changed. Upon increasing the scan rate, the anodic peak moves to more positive

Figure 30. Circumrotation of the macrocyclic polyether component of the [2]catenane 18^{4+} can be controlled oxidizing/reducing reversibly the tetrathiafulvalene unit [59].

potentials, while the cathodic one shifts to less-positive values. These observations indicate that the oxidation/reduction of the TTF unit is accompanied by the circumrotation of the macrocyclic polyether through the cavity of the tetracationic cyclophane and that this co-conformational change is occurring on the time scale of the electrochemical experiment. Indeed, after monooxidation, the newly formed monocationic TTF unit is expelled from the cavity of the tetracationic cyclophane, and is replaced by the neutral dioxynaphthalene unit. After reduction, the original co-conformation is restored as the neutral TTF unit replaces the dioxynaphthalene unit inside the cavity of the tetracationic cyclophane [60, 61].

The [2]catenane 19^{4+} incorporates (Figure 31) a macrocyclic polyether containing two dioxybenzene units, and a tetracationic cyclophane comprising a bipyridinium and a *trans*-bis(pyridinium)ethylene unit [36a, 62]. The ^1H NMR spectrum $[(\text{CD}_3)_2\text{CO}, 213 \text{ K}]$ of 19^{4+} shows the signals for two distinct co-conformations in a ratio of 92:8. In the major isomer, the bipyridinium unit is located inside the cavity of the macrocyclic polyether and the *trans*-bis(pyridinium)ethylene unit is posi-

Figure 31. Circumrotation of the tetracationic cyclophane component of the [2]catenane 19^{4+} can be controlled reversibly by reducing/oxidizing electrochemically its bipyridinium unit [36a].

tioned alongside. The first two reduction waves in the cyclic voltammogram of the 'free' tetracationic cyclophane occur at -0.31 and -0.43 V versus SCE. They correspond to the first monoelectronic reductions of the bipyridinium and of the *trans*-bis(pyridinium)ethylene unit, respectively. In case of the [2]catenane, these two waves are shifted to more negative potentials and occur at -0.39 and -0.49 V versus SCE. These observations indicate that the bipyridinium unit is preferentially located inside the cavity of the macrocyclic polyether (Figure 31), and its reduction is more difficult than in the case of the 'free' tetracationic cyclophane. However, once this unit is reduced, the tetracationic cyclophane circumrotates through the cavity of the macrocyclic polyether moving the *trans*-bis(pyridinium)ethylene unit inside, as shown by comparison of its reduction potential with that of a catenane model compound [36a]. Upon back oxidation of the reduced bipyridinium unit, the original equilibrium between the two co-conformations associated with the [2]catenane 19^{4+} is restored.

As described in detail in Volume III, Part 2, Chapter 8, electrochemically induced movements can also be obtained in the [2]catenate containing Cu^+ ions [63, 64].

7.5.4 Photochemically Controlled Ring Motions

The only example presently available of photochemically controllable ring motion through an electron transfer reaction in a catenane structure concerns a Cu^+ -based [2]catenane, which is discussed in Volume III, Part 2, Chapter 8 [64]. Examples of catenanes containing *cis-trans* photoisomerizable units and where ring motions can be photochemically controlled are also known [65].

7.5.5 Chemically Controlled Ring Motions

Some examples of chemically controlled ring motions in catenanes through electron transfer or charge transfer processes have been reported.

In the case of the previously discussed [2]catenane **18**⁴⁺ shown in Figure 30, switching from the more stable translational isomer (which contains a TTF unit inside the tetracationic cyclophane) to a less stable one can be obtained not only by oxidation of the TTF unit, but also by addition of *o*-chloroanil. ¹H NMR spectroscopy shows that *o*-chloroanil gives an adduct, presumably CT in nature, with the TTF unit which locks this unit alongside the cavity of the cyclophane. On addition of $\text{Na}_2\text{S}_2\text{O}_5$ the adduct is destroyed and the original isomer with the TTF unit inside the cavity of the cyclophane is restored [59, 66].

The [2]catenane **20**⁴⁺ incorporates (Figure 32) a macrocyclic polyether containing two dioxybenzene units and a tetracationic cyclophane comprising a bipyridinium and a diazapyrenium unit [67]. X-ray crystallographic analysis of this compound revealed that the macrocyclic polyether encircles exclusively the diazapyrenium ring system in the solid state. The ¹H NMR spectrum [$(\text{CD}_3)_2\text{CO}$, 193 K] of **20**⁴⁺ shows the signals for two distinct co-conformations in a ratio of 96:4. In the major isomer, the diazapyrenium ring system is located inside the cavity of the macrocyclic polyether, and the bipyridinium unit is positioned alongside. The ability of *n*-hexylamine to form adducts (most likely of CT nature) with the diazapyrenium moiety can be exploited to displace the equilibrium between the two co-conformations in favor of the isomer having the diazapyrenium unit alongside the cavity of the macrocyclic polyether [68]. The differential pulse voltammogram (MeCN, 298 K) of **20**⁴⁺ shows two peaks at -0.31 and -0.57 V versus SCE for the monoelectronic reduction of the alongside bipyridinium unit and of the inside diazapyrenium unit, respectively. After the addition of *n*-hexylamine, the first peak shifts by -60 mV to a potential that corresponds to the monoelectronic reduction of a bipyridinium unit encircled by the dioxybenzene-based macrocyclic polyether [36a]. Similarly, the second peak shifts by -20 mV to a potential that is associated with the monoelectronic reduction of a diazapyrenium unit interacting with *n*-hexylamine. On addition of $\text{CF}_3\text{SO}_2\text{H}$, protonation of *n*-hexylamine occurs. As a result, the adduct formed between *n*-hexylamine and the diazapyrenium unit of the [2]catenane is destroyed and the original equilibrium between the two co-conformations associated with **20**⁴⁺ is restored. The differential pulse voltammogram recorded after the addition of $\text{CF}_3\text{SO}_2\text{H}$ is identical with that recorded before the addition of *n*-hexylamine [68].

Figure 32. Circumrotation of the tetracationic cyclophane component of the [2]catenane 20^{4+} can be controlled reversibly by adding/protonating *n*-hexylamine which forms a charge-transfer adduct with the diazapyrenium unit of this [2]catenane [68].

7.6 Molecular-Level Machines

The unique architecture of rotaxanes and catenanes (as well as pseudorotaxanes; see Volume III, Part 2, Chapter 6) lend themselves to the occurrence of large-amplitude motions by their component parts—a property reminiscent of the movements displayed by the working parts of machines in the macroscopic world. The concept of machine at the molecular level is not a new one. Our body can be looked upon as an extremely complex ensemble of molecular-level machines that power our movements, repair damage, and orchestrate our inner worlds of thought, sense, and emotion [69]. The challenge of constructing artificial molecular machines was posed for the first time by Feynman [70] in his famous address, *There is Plenty of Room at the Bottom*, to the American Physical Society in 1959. In his address, he raised a number of interesting issues, such as:

“... What are the possibilities of small but movable machines?... An internal combustion engine of molecular size is impossible ... Other chemical reactions, liberating energy when cold, can be used instead ... What would be the utility of such machines?...”

Although some intriguing examples of simple molecular-level machines (e.g., a phototweezer) [71] were reported during the 1980s, it has only been during the past few years that, thanks to the rapid growth of supramolecular chemistry [20], the issues raised by Feynman have become hot topics in contemporary scientific research [30–33, 41]. Catenanes and rotaxanes are indeed providing cogent answers to the first of Feynman’s questions: when the motions of their component parts can be induced and controlled by external inputs of energy, such exotic chemical systems can certainly be viewed as simple molecular machines. As Feynman [70] predicted, the input of external energy to make such machines work has to be a cold chemical reaction. What apparently he did not predict, somewhat amazingly, is the possibility that the required chemical energy can be provided by electrochemical reactions and, most importantly, by light excitation.

Reversible structural rearrangements governed by external inputs are interesting not only from the viewpoint of mechanical movements, but also for information processing at the molecular level. Reversible switching between two “states” (see Figures 13 and 29) corresponds to a binary logic behavior. Indeed, molecular-level information processing [72] seems to be a possible answer to Feynman’s question [70] about the utility of such “*small but movable machines*”. Although the term “molecular computer” is still an emotive one among chemists, the continuous advances in the field of molecular electronics [73] and the fact that today’s silicon-based technology is rapidly approaching the upper limits of its physical capabilities [74] leads to the prediction that the chemical (molecular-level) computer is likely to replace our present technology by the year 2025 [75].

We would also like to point out that, similar to their macroscopic counterparts, molecular-level machines have to be organized structurally and work as functionally integrated, multicomponent systems [32, 41a]. The first step is to produce an accurate design of the working mechanism of the machine, followed by a search for those components that exhibit the required properties, and then finally to find the means to assemble them in the required order. A clear example of the level reached by this kind of research is given by the [2]rotaxane **16**⁴⁺ shown in Figures 17–19, which was obtained by assembling in a predetermined sequence as many as six different components, each one exhibiting suitable spectroscopic and redox properties [47].

7.7 Modified Electrodes and Heterosupramolecular Systems

The investigation of rotaxanes and catenanes in solution is not only of fundamental importance to understand their complex behavior, but it also represents a starting

Figure 33. Pictorial representation of the preparation of a surface-attached catenane by coupling self-assembly in solution with chemisorption onto a solid support [83].

point for the construction of molecular-level machines. A solution, however, contains a huge number of molecules which behave incoherently since they cannot be addressed individually, and hence controlled [76]. It seems reasonable therefore that, before functional supramolecular assemblies can be employed in a machine-like manner, they have to be interfaced with the macroscopic world by ordering them in some way. The next generation of molecular machines will need to be organized at interfaces [77] or deposited on surfaces [78] so that they can behave coherently, either in parallel or in series, and can also be addressed on the nanometer scale [79].

The self-assembly of molecular components in solution can be coupled (Figure 33) to deposition techniques for obtaining surface-attached supramolecular and interlocked molecular systems. Among the most interesting examples are a monolayer constituted of the tetracationic cyclophane **1**⁴⁺ catenated onto a gold surface by means of a molecular thread bearing thiol groups at both ends [80], and a polyrotaxane deposited as a film onto an electrode by electropolymerization [81]. In the latter case, rotation of the ring component around the polymer-derivatized thread, confined to the film, can be electrochemically triggered.

Another interesting approach is provided by the emerging field of heterosupramolecular chemistry [82]. Heterosupramolecules, that is supramolecular systems in which one or more components are in the condensed phase (e.g., nanocrystals), are expected to offer considerable advantages from the viewpoints of molecular organization and addressability. Following the strategy outlined in Figure 33, hetero[2]catenanes in which TiO₂ or SnO₂ nanosized particles are incorporated as a part of one of the ring components have been prepared, and are presently the subject of photochemical and electrochemical investigations [83].

7.8 Conclusions

CT interactions and electron transfer processes play a fundamental role in the chemistry of rotaxanes and catenanes. CT interactions are often responsible for the driving forces that lead to the syntheses of these compounds; such interactions “live on” when the components have been interlocked, and therefore contribute to determine the actual structure of the resulting compound. Because of the presence of CT interactions, the electronic absorption and emission spectra, as well as the electrochemical behavior, of many rotaxanes and catenanes exhibit characteristic features, quite different from those exhibited by the separated components.

In interlocked compounds such as rotaxanes and catenanes, electron-donor and -acceptor units not only cause the presence of CT interactions, but are also responsible for the occurrence of intercomponent and intermolecular oxidation and reduction processes. Such processes weaken or even destroy the CT interactions that stabilize the structure of the compound, with a consequent change in its conformation. External inputs, like electrons or photons, can be used to cause the redox processes and the structural rearrangements that follow. Suitably designed rotaxanes and catenanes can therefore exhibit machine-like movements that correspond to a binary logic behavior.

Since reliable and efficient strategies for the synthesis of rotaxanes and catenanes have been established, current research is focused on functionalization of the component parts of these interlocked species and on the construction of increasingly complex compounds in the search for new and valuable properties.

 76. An intriguing question about molecular machines is to establish which components are moving and which are not. Since, in solution, the motions of the molecular components cannot be referred to a fixed reference point, the question cannot even be addressed. One answer to this question is the immobilization of one or more components to a fixed frame such as a surface.

8 Metal-Assembled Catenanes, Rotaxanes, and Knots

*Nicola Armaroli, Jean-Claude Chambron, Jean-Paul Collin,
Christiane Dietrich-Buchecker, Lucia Flamigni, Jean-Marc Kern, and
Jean-Pierre Sauvage*

8.1 Introduction

Twenty years ago, the only interlocking ring systems (catenanes) that had been made and convincingly characterized were those prepared by Schill and his coworkers [1]. In biology, DNA had also been shown to form simple to complex catenanes during certain processes or under the action of topoisomerases [2]. It was difficult to imagine that synthetic or natural interlocking rings would display any kind of interesting property related to electron transfer. Today, catenanes are almost common molecules, and they have been the subject of numerous studies dealing with electrochemistry, photoinduced electron transfer, and controlled molecular motions. This change of situation reflects the rapid evolution of the field of catenanes, rotaxanes, and knots [3]—part of the general area called *chemical topology* [4].

The synthesis of these chemical objects has been made possible thanks to the introduction of template reactions, either using transition metal complexes or organic functions as templating cores. The concept of templated synthesis itself was introduced several decades ago, in particular by Busch and his coworkers [5], simultaneously to the accidental preparation of a macrocyclic nickel(II) complex from very simple organic precursors [6]. The recognition that a transition metal can be used to gather various organic fragments in its coordination sphere, maintain and orient them in a given geometry so as to allow the preparation of well-defined and relatively sophisticated multifunctional ligands after the appropriate covalent bonds have been formed, is indeed conceptually very important. It has opened the door to many multicomponent compounds incorporating one or several transition metal centers. More importantly, in the present context, it has provided the precursor ideas which allowed to make the first [2]catenane (consisting of two interlocking rings) complexed to a transition metal center more than 15 years ago [7].

Catenanes have a nonplanar molecular graph, which means that it will be impossible to draw their backbone on a sheet of paper without introducing crossing

points (two for a [2]catenane), regardless of the deformation that the chemical bonds can undergo (bond angles and lengths). In this respect, catenanes are really three-dimensional species. They are thus very well adapted to the complexation of transition metals which, in most cases, interact with ligands disposed in a three-dimensional space and not only in a plane. As will be discussed in this chapter, this property of controlling the coordination polyhedron of the metal is one of the characteristics of the present molecules. By imposing a given arrangement, and in particular a tetrahedral geometry, the electrochemical properties of the corresponding complexes are of special interest. A striking example is that of stable nickel(I) complexes, whose relatively easy isolation relies on the special stabilization of low oxidation states (Co^{I} , Ni^{I} , or Cu^{I}) provided by a tetrahedral arrangement.

Interlocking structure provides to the corresponding multicomponent assemblies the ability to move and rearrange by gliding one given ring within another ring with which it is interlocked, or by translating a wheel along an axle which threads it. This unique feature allows reversible rearrangements of the coordination sphere (from tetrahedral to 5-coordinate or more, and vice versa). Electron transfer, in this case, is followed by motion: a redox process triggers a controlled rearrangement of the metal ligands set, this large amplitude motion being facilitated by the interlocking nature of the compounds.

Another specificity of catenanes and rotaxanes relates to the marked flexibility of the molecules once demetallated, and to the very large geometric differences between the complexes and free ligands. Such a property can be utilized to test electron transfer theories if the molecules incorporate donor and acceptor groups (porphyrins, in general), whose distance and mutual orientation can be dramatically modified at will by metallating or demetallating the appropriate coordination sites. Interestingly, most—if not all—of the compounds described in the present chapter display novel photophysical and photochemical properties, leading to intramolecular energy or electron transfer between given components of the system.

8.2 Electrochemical Properties of Metallocatenates and Knots

8.2.1 Introduction

A catenane consists of two or several interlocked macrocycles, whereas a trefoil molecular knot is formed by a single closed molecular thread displaying three crossing points. The particular class of catenanes and molecular knots that has been synthesized and studied, combines the topological properties of systems having a nonplanar graph [1a, 4a, 8] with the complexing ability of 1,10-phenanthroline-type chelates or terpyridine-type chelates [9, 10]. Therefore, they can behave as ligands, and the resulting complexes are called catenates.

In most of the metallocatenates described here, the coordinating rings include 2,9-di-*p*-phenyl-1,10-phenanthroline (dpp) derivatives as complexing subunit. The special arrangement of the coordinating fragments that form the complexing core is

due to the nature of these fragments. By complexation to a metal, two dpp subunits lock together, while binding the metal, and adopt an entwined topography. The highly rigid and encaging system thus obtained favors distorted tetrahedral geometries. The aromatic character of the ligands and their strong π - π accepting ability, together with the preferred shape of catenates, are expected to highly stabilize low oxidation states, for two different reasons. The first factor, π - π donor-acceptor character of the coordinating subunits, is really stabilizing, whereas the second factor corresponds to a strong destabilization of high oxidation states, due to the poor ligand field of tetrahedral geometry and to steric factors that disfavor 5-coordinate complexes. The topography of the system [10] is thus such that low oxidation states will be preferred to high valence states. The topographic properties of a complex are related to the shape of the molecule and to the bond lengths and angles within the coordination site. The stability of the complexes (kinetic and thermodynamic) will now be measured by the topology of the ligand: the interlocking of the rings prevents the dpp subunits from dissociating, and thus greatly contributes to inhibiting dissociation of the complexes. Thus, complexes of unusually low valence states may be made and isolated with interlocked ligands, whereas the corresponding acyclic dpp complexes are too labile to be studied.

Electrochemical and photophysical properties of metallocatenates are strongly dependent on the geometry of the coordinating sphere of the central metal(s). In this section, which is devoted to the electrochemical properties of metallocatenates, we will first describe the particular properties of various [2]catenates in which the metal is tetracoordinated, that is the constitutive macrocycles of the [2]catenates contain a dpp moiety each. The interaction of metal centers in homodinuclear [3]catenates and in molecular knots will be developed in Sections 8.2.5 and 8.2.6. In Section 8.2.7, the electrochemical properties of a ruthenium [2]catenate will be discussed. In that case, each ring includes a tris-chelating moiety, a terpyridine (tpy), providing an octahedral environment to the templating metal. Catenates formed with homo- and/or heterobischelating macrocycles will deal with the field of molecular machines, and their particular properties are described in Section 8.5.

8.2.2 Metallo[2]catenates in which the Metal is in a Tetrahedral Environment: Stabilization of Low Oxidation States

The basic framework of the catenanes (Cat) described in this section (free ligand and metal complexes) is presented in Figure 1.

For comparison, 2,9-di-*p*-anisyl-1,10-phenanthroline **1** (dap), which can be considered as the acyclic analogue of the various investigated catenanes, has also been examined (Figure 2). In particular, the ability of dap to stabilize low oxidation states has been tested in parallel to that of Cat. The propensity of aromatic polyimine chelates to stabilize the low oxidation states was recognized long ago. The most studied cases are probably those of Fe^{II} and Cu^{I} . For the former, the stability of the tris-bipyridine (bpy) complex was demonstrated in particular by the high redox potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple (+1.026 V versus NHE in 1 M H_2SO_4 [11] and +1.012 V versus SCE in CH_3CN [12].

Figure 1. Schematic framework of a dpp-containing metallocatenate (a), of the related free ligand (b) and of a metallated molecular knot (c).

The question related to the oxidation number of the transition metal in certain highly reduced compounds was also addressed a long time ago [13–15]. It was noticed that, in particular, the 18-electron rule was no longer valid for a variety of complexes [16]. Clearly, complexes of metals in formally negative or zero oxidation states are in some cases best regarded as complexes of the ligand anion. Catenanes and their acyclic analogue dap contain strong π -acceptor ligands of the phenanthroline (phen) type, and are thus expected to behave as discussed above. In addition, a very important characteristic of catenanes and, to a lesser extent, of dap is of geometric origin. The presence of bulky substituents α to the nitrogen atoms of the constitutive chelates inhibits the formation of octahedral complexes, but favors tetrahedral geometries. Due to the presence of two aromatic substituents α to the chelates, the metallocatenate (noted $[\text{M.Cat}]^{n+}$, M being the metal and Cat the catenane ligand) and $[\text{M}(\text{dap})_2]^{n+}$, adopt “an entwined topography”, which leads to

Figure 2. Representation of macrocycles, of the corresponding acyclic ligand **dap** (1), and of the different metallated [2]catenanes.

highly encaged and rigid systems. This particular geometry was evidenced by X-ray crystal analysis of the molecular structure of various catenanes [17]. In addition, the topological link of catenanes (interlocked ligands) inhibits separation in two coordinating subunits when they are complexed to a given cationic species. These characteristics enable Cat to bind strongly to transition metals, even in their lowest oxidation states. Comparison of Cat and dap complexes will evidence these topological factors, since the geometry around the complexed species M^{n+} is likely to

Table 1. ^a Cu^{2+/+} redox potentials^b of various copper [2]catenates

Compound	E ⁰ (V)	Compound	E ⁰ (V)
Cu^{2+/+}	1.05 ^c	Cu.Ru.8³⁺	0.58
Cu.4⁺	0.685	CuRuRu.9⁵⁺	0.64
Cu.5⁺	0.565	CuRuZn.9⁵⁺	0.68
Cu.6⁺	0.575	CuRuCo. 9⁵⁺	0.66
Cu.7⁺	0.70 ^d	CuRuCu.9⁵⁺	0.61
		CuRuFe.9⁵⁺	0.63

be virtually identical for [M.Cat]ⁿ⁺ and [M(dap)₂]ⁿ⁺. Furthermore, Cat is able to complex transition metals even after having accepted one or two electrons, whereas dap complexes dissociate much more readily upon exhaustive reduction. Here again, this is related to the different topological properties of the two coordinating systems.

8.2.3 Copper [2]catenates

Copper [2]catenates were the most widely studied metallocatenates. Some are shown in Figure 2 in which the complexing core is formed by two dpp subunits. **Cu.5⁺** is a [2]catenate formed with two interlocked identical 30-membered macrocycles **3**. A copper [2]catenate made from a smaller homologue of **3**, the 27-membered ring **2**, has also been synthesized and studied [7a]. **Cu.5⁺** and the corresponding free ligand **5** [7b], are the archetypes of this wide family [10] of topologically nontrivial molecules formed by the catenanes. **2** [7a] and **3** [7b] differ only by the length of the polyoxoethylene chains which connect the para positions of the dpp moieties. The design of **6** [18] is noticeably different, the 56-membered ring including two 2,9-bis (*p*-biphenyl)-1,10-phenanthroline units. In **Cu.6⁺** only one chelating moiety is used for metal complexation, the other one being available for the coordination of another metal ion, and opening the way to the iterative construction of polycatenanes. In **Cu.7⁺**, the 34-membered macrocycle includes a disulfide bridge, allowing the chemisorption of this species onto a gold surface [19, 20]. **CuRu.8³⁺** [21] and **CuRuM.9⁵⁺** [22] (M = Ru²⁺, Zn²⁺, Co²⁺, Fe²⁺, Cu²⁺) are dimetallic or trimetallic complexes respectively, containing interlocking rings.

In CH₃CN or CH₂Cl₂, all copper(I) [2]catenates are reversibly oxidized to the divalent complexes (Figure 3). The oxidation potentials are high (~0.6 V versus SCE), making the Cu^{II} species relatively strong oxidants.

The present systems are noticeably different from [Cu(*bpy*)₂]⁺ for which the Cu^{2+/+} couple has a redox potential value of 0.19 V versus SCE [23]. The relatively high Cu²⁺/Cu⁺ redox potentials of the presently studied compounds are in good agreement with earlier systems: 6,6'-dimethyl-2,2'-bipyridine [24] (dmbp) or 2,9-

Figure 3. Cyclic voltammograms of bis-chelate copper complexes (a) $[\text{Cu}(\text{phen})_2]^+$ and (b) $[\text{Cu}(\text{dmbp})_2]^+$ in $\text{CH}_3\text{CN}-(n\text{-C}_4\text{H}_9)_4\text{NClO}_4$ (0.1 M), and (c) of copper-catenate Cu.5^+ in CH_3CN for oxidation, in DMF for reduction. Oxidation on Pt, reduction on the hanging mercury electrode.

dimethyl-1,10-phenanthroline complexes [24–26]. The particular redox properties of all those $\text{Cu}^{2+}/\text{Cu}^+$ couples can be assigned to geometric factors [27]. Cu.5^{2+} was readily and quantitatively electrogenerated from the copper(I) precursor [28]. The deep green catenate is stable in solution and can be crystallized. The low-energy band at 666 nm ($\epsilon = 820 \text{ M}^{-1} \text{ cm}^{-1}$) is ligand field in nature, this also being observed in related Cu^{II} complex $[\text{Cu}(\text{dpp})_2](\text{ClO}_4)_2$ [29], the structure of which showed a pseudotetrahedral geometry of the Cu^{II} center. Despite the closeness of the structures of Cu.4^+ and Cu.5^+ (they differ only by the length of the polyoxoethylene chains which connect the *para* positions of the dpp units) the oxidation potential of Cu.4^+ is noticeably more positive (124 mV) compared to that of the Cu.5^+ homologue [23]. This anodic shift of the redox potential can be explained by the more pronounced steric constraints in the Cu.4^+ homologue, preventing re-

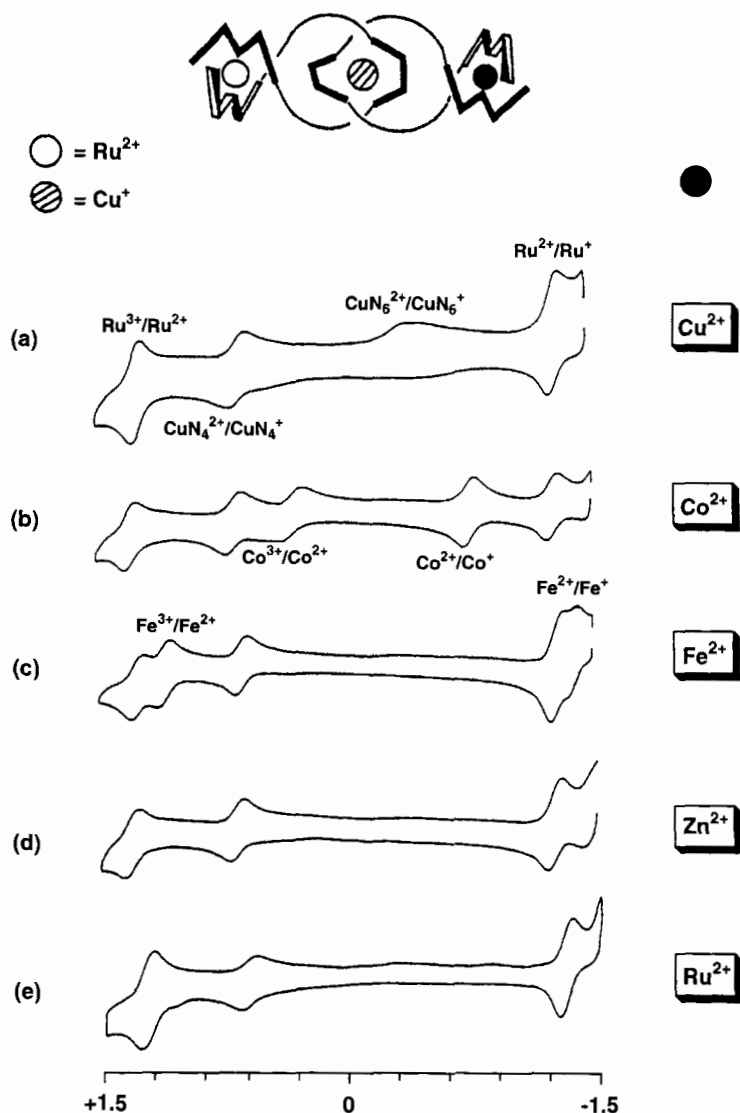

Figure 4. Cyclic voltammetry studies of the CuRuM.9^{5+} catenates containing two (a, e) or three (b, c, d) different metals, and clearly showing the distinct electrochemical response of each unit. The formal $\text{Ru}^{2+}/\text{Ru}^+$ couple corresponds to a ligand-localized process.

arrangement of the coordination geometry after oxidation. For the heterodimetallic and heterotrimetallic copper-catenates [21, 22], $\text{Cu}^{2+}/\text{Cu}^+$ redox potential values collected in Table 1 show minimal dependence (if any) on the various clipping metals (Figure 4). Reduction of copper(I) [2]catenates was only studied in detail [7b, 23, 28] for Cu.5^+ (Table 2).

Table 2. Electrochemical properties of **Cu.5**⁺ versus free Cu⁺ ion [23]^a

Cu.5 ⁺	E _{1/2} (V)	Free metal	E _{1/2} (V)
+2/+1	0.565 (CH ₃ CN)	+1/0	−0.31 ^{b,c} (CH ₃ CN)
+1/0	−1.650 (DMF)	+1/0	−0.53 ^{c,d} (CH ₃ CN)
0/−1	−1.860 (DMF)		

^a All potentials refer to SCE; the systems are reversible.^b Pt electrode.^c See Ref. [30].^d Polarography at the dropping mercury electrode.

Comparison of the reduction process with that of the acyclic analogue [Cu(1)₂]⁺ allowed to discriminate topographical and topological contributions to the overall electrochemical behavior of **Cu.5**⁺. For **Cu.5**⁺ (as for [Cu(1)₂]⁺), two reversible one-electron transfers are observed at very negative potentials (−1.650 and −1.860 V versus SCE for **Cu.5**⁺). This behavior is distinctly different from that of other complexes containing unsubstituted chelates, like *bpy* and *phen* (Figure 3). For instance, the following reductive dissociation takes place at −0.262 V [23]:

In the case of the *phen* complex, reduction of the monovalent state leads to copper metal, the initial electron transfer occurring either in the Cu 4s orbital or via a *phen* π^* orbital. Fast dissociation follows this monoelectronic reduction step. The redox orbitals involved during the reduction process of the copper catenate are likely to be ligand-localized. This is also supported by the small difference between the redox potentials of the Cu^{+1/0} and Cu^{0/−1} couples ($\Delta E_{1/2} \sim 200$ mV). Electrolysis of **Cu.5**⁺ in the cavity of an EPR spectrometer confirms the radical anion nature of the formally copper(0) complex obtained by one-electron reduction of the catenate: $g = 2.000 \pm 0.002$, $\Delta H = 39$ G.

The reduction potentials of **Cu.5**⁺ and [Cu(1)₂]⁺ are almost identical for both of the formally Cu^{+1/0} and Cu^{0/−1} couples, but the kinetic stability of the reduced catenate is dramatically more pronounced than that of its acyclic analogue. At low scan rates (<10 mV s^{−1}), even the first reduction of [Cu(1)₂]⁺ becomes irreversible, whereas the corresponding process for **Cu.5**⁺ remains completely reversible [7b, 28]. Furthermore, the electrochemical reduction of **Cu.5**⁺ allows the build-up of the formally zero-valent complex indicated by a deep-blue solution ($\lambda_{\text{max}} = 603$ nm, $\epsilon = 5300$ M^{−1} cm^{−1}; $\lambda_{\text{max}} = 840$ nm, $\epsilon = 4300$ M^{−1} cm^{−1}) (Figure 5).

It is noteworthy that, due to the topologically different properties of the copper-catenate and the copper-entwined complex [Cu(dap)₂]⁺, electrolysis of the second leads only to copper metal and free dap.

Figure 5. Reduction of Cu.5^+ : successive electronic spectra during electrolysis (DMF, -1.73 V, Au grid). $t = 0$ (—), 25 min (---), 90 min (— · —).

8.2.4 Electrochemical Study of Various Monometallated Catenanes in which the Metal is Tetracoordinated

Catenane **5** was here again mainly used for this study, and comparison of the electrochemical behavior of the catenate complexes and the analogous complexes of the acyclic ligand **1** will be particularly emphasized in this section. The cations include Li^+ , H^+ , Co^{2+} , Ni^{2+} , Zn^{2+} , Ag^+ , Cd^{2+} , and Pd^{2+} . The electrochemical data are collected in Table 3.

The redox processes observed might involve either metal-centered reactions (d or s orbitals) or electron transfer to the organic ligand (π^* orbitals of the dpp subunits). In some cases, the assignment can be made via EPR measurements and redox potential values. If the $\text{Cu}^{2+}/\text{Cu}^+$ couple always involves a metal-centered redox process, the electron transfer to Li.5^+ clearly occurs on the ligand moiety. No distinction can be made between both pathways for many of the complexes studied.

Lithium-catenate and free ligands [28]

Catenane **5** is insoluble in CH_3CN . Ligand **1** is fairly soluble in this medium, and is expected to display electronic properties similar to those of catenate **5**:

Li.5^+ is stable in CH_3CN , and shows two reduction waves, but only the first (-1.80 V) is reversible. These electron transfers were observed on both Hg and Pt at

Table 3. Electrochemical properties of various M_5^{n+} catenates: $E_{1/2}$ values (V) determined by cyclic voltammetry or by polarography^a

Redox process	Li	H	Co	Ni	Zn	Ag	Cd	Pd

^d Polarography at the dropping mercury electrode.

^e Only Pt electrode.

the same potential values, and correspond to reduction of the catenate moiety, free Li^+ being reversibly reduced to Li-Hg at -1.96 V under identical conditions.

Electrolysis of Li.5^+ at -1.90 V leads to the build-up of a red species which subsequently decomposes in solution. This compound is likely to be the lithium-stabilized radical anion $[\text{Li}^+.\text{5}^{\bullet-}]^0$. The interlocking nature of **5** allows complexation of Li^+ , whereas **1** is unable to form any stable complex.

Cobalt-catenate [28]

Two perfectly reversible one-electron reduction steps are observed for Co.5^{2+} , at -0.53 V ($\text{Co}^{2+/+}$) and -1.205 V ($\text{Co}^{+/0}$). Comparison of the electrochemical properties of the cobalt catenate with the previously reported data for cobalt *bpy* or phen complexes [31, 32] shows here again a strong stabilization of the reduced states, Co^{I} and Co^{II} . Other sterically constrained polyimine ligands also lead to stabilized monovalent cobalt complexes [33–37]. Remarkable also is the drastic structural effect of the catenate on the $\text{Co}^{3+/2+}$ redox potential: whereas *bpy* or phen complexes of cobalt(II) can easily be oxidized to octahedral cobalt(III) [36, 38], the redox potential value of the $\text{Co}^{3+/2+}$ couple being close to 0 V, no oxidation peak is observed for Co.5^{2+} prior to ligand oxidation ($E_p > 1.6$ V). The destabilization effect of Co^{III} due to tetrahedral environment provided by the entwined and interlocked structure of **5** is thus very large (>1.5 V).

Nickel-catenate [28, 39]

A surprising stabilization of monovalent nickel occurs by coordination to **5**. In CH_3CN , the redox potential of the $\text{Ni}^{2+/+}$ couple is -0.18 V. The same explanation as that put forward for Co complexes applies here to account for the stabilization of Ni^{I} complex of **5**. The potential stability range of the Ni^{I} -catenate (-1.32 to -0.18 V) is remarkably broad. The behavior of Ni.5^{2+} is strikingly different from that of *bpy* nickel(II) complexes [40–42]. In the case of unsubstituted *bipy* ligands, electrochemical reduction of $[\text{Ni}(\text{bpy})_3]^{2+}$ leads directly to $[\text{Ni}(\text{bpy})_3]^0$ in a two-electron process ($E_{1/2} = -1.3$ V) [40], and monovalent nickel is not observed.

Monovalent nickel-catenate Ni.5^+ can be prepared by electrolysis of the divalent precursor. An EPR study clearly shows that this compound is a true d^9 nickel(I) complex [39] ($g_1 = 2.388$, $g_2 = 2.143$, and $g_3 = 2.071$, CH_2Cl_2 , frozen solution). X-ray studies of $(\text{Ni}^{\text{I}}.\text{5})(\text{ClO}_4)$ and $(\text{Ni}^{\text{II}}.\text{5})(\text{BF}_4)_2$ [43] revealed a pronounced difference for the environment of the metal centers in these two structures. Whereas the ligand system is perfectly well adapted to a tetrahedral geometry for monovalent nickel, the divalent state leads to a strongly distorted structure, in accordance with a d^8 configuration which is not likely easily to accommodate a tetrahedral environment. Accordingly, the two chelate planes of the nickel(I) catenate being perpendicular to one another, no intramolecular stacking interactions between aromatic groups are

observed, whereas in the Ni^{II} case strong π - π interactions between phenyl rings and phenanthroline nuclei take place. Due to almost identical topographical properties of $[\text{Ni}(\text{1})_2]^{2+}$ and Ni.5^{2+} , the redox potential values of the corresponding $\text{Ni}^{2+}/+$ couples are equal. However, the behavior of both compounds with respect to re-oxidation by O_2 is drastically different.

The reactivity of $[\text{Ni}(\text{1})_2]^{2+}$ is much more pronounced than that of nickel(I) catenate. In CH_2Cl_2 , the bimolecular rate constants corresponding to the reaction of the monovalent nickel complex with O_2 are as follows:

The topological properties of Ni.5^+ (interlocked ligands) thus have a dramatic influence on its kinetic inertness.

Silver-catenate [28]

The silver(I) catenate Ag.5^+ is certainly one of the most difficult silver(I) complexes to reduce. The reduction potential of free Ag^+/Ag^0 at the dropping mercury electrode determined in CH_3CN is +0.420 V. A noticeable ligand effect is observed for $[\text{Ag}(\text{1})_2]^+$, since a significant shift of its reduction potential (235 mV) to less positive values is observed. More remarkable is the behavior of the silver catenate. Its reduction occurs at -0.70 V in CH_3CN , and is thus 1.12 V more cathodic than that of free Ag^+ . Thus, the topological effect estimated by comparing the reduction potentials of $[\text{Ag}(\text{1})_2]^+$ and Ag.5^+ is 0.885 V. This particular property of the silver(I) catenate was used for the evaluation of the topological characteristics of different polypyrrole matrices built around dpp moieties [44].

Zinc-catenate [28]

The reduction processes of both $[\text{Zn}(\text{1})_2]^{2+}$ and Zn.5^{2+} occur in two one-electron steps in CH_3CN or in CH_2Cl_2 , with a relatively broad (300-mV) stability range of the formally monovalent zinc complexes (Figure 6).

Exhaustive electrolysis of the zinc(II) catenate at the first reduction wave plateau (-1.1 V) leads to the formation of a pink-red solution ($\lambda_{\text{max}} = 530 \text{ nm}$, $\epsilon \sim 1000 \text{ M}^{-1} \text{ cm}^{-1}$) of the corresponding monovalent complex. EPR measurements performed on a frozen solution of the electrochemically generated monovalent zinc catenate show the presence of a paramagnetic radical species ($g = 2.00246$, $\Delta H = 11.46 \text{ G}$). The reduced states Zn.5^+ and Zn.5^0 , containing formally monovalent and zerovalent zinc, respectively, are better described as zinc(II)-stabilized anion radicals.

Cadmium-catenate [28]

In CH_3CN , free Cd^{2+} , $[\text{Cd}(\text{1})_2]^{2+}$ and Cd.5^{2+} are reduced in a two-electron process at -0.285, -0.400 and -0.850 V, respectively. In each case, the divalent cationic species is reduced to cadmium amalgam. In CH_2Cl_2 and on Pt, the electrochemical

Figure 6. Cyclic voltammetry (CV) on platinum and polarography at the dropping mercury electrode (DME) of $[\text{Zn}(\mathbf{1})_2]^{2+}$ in 0.1 M CH_2Cl_2 - $(n\text{-C}_4\text{H}_9)_4\text{NClO}_4$ (0.1 M) (scan rate for CV, 40 mV s^{-1} ; E versus $\text{Ag}/\text{Ag}_3\text{I}_4^-$).

behavior of $\text{Cd}(\mathbf{5})^{2+}$ is different. The corresponding cyclic voltammetry indicates that reduction occurs in two steps at -1.15 V and -1.36 V. The monovalent and zerovalent complexes could not be built-up in solution. However, it is remarkable that the mono- and direduced cadmium catenates could be observed as transient species when the dissociation reaction is not favored by amalgam formation. Here again, this particular property mainly originates from the interlocking of the ligand, since reduction of $[\text{Cd}(\mathbf{1})_2]^{2+}$ leads only to complete dissociation with no observable transient species.

Palladium-catenate [45]

In the case of all of the catenate complexes discussed above, the ligand imposes a more or less distorted tetrahedral geometry to the metal center. However, complexation of Pd^{2+} with **5** follows a different route. Insertion of Pd^{2+} into **5** yields the monocation $[\text{Pd}^{\text{II}}(\mathbf{5}\text{-H})]^+$ via *ortho*-metallation of one of the phenyl rings to give planar coordination by an N_3C donor set. The structure of $[\text{Pd}^{\text{II}}(\mathbf{5}\text{-H})]^+$ is a compromise between the stereochemical and conformational preferences of metal and ligand where the disparity between the requirements of square planar Pd^{II} and tetrahedral **5** is resolved by *ortho*-metallation. $[\text{Pd}^{\text{II}}(\mathbf{5}\text{-H})]^+$ shows a reversible oxidation at $+0.55$ V versus Fc^+/Fc (Fc = ferrocene) assigned to a $\text{Pd}^{3+/2+}$ couple. Two reversible reductions are observed for the palladium complex at extreme cathodic potentials, $E_{1/2} = -1.95$ and -2.23 V) versus Fc^+/Fc .

In conclusion, from this electrochemical study, one can conclude that the most

Figure 7. Synthetic strategy to obtain a [3]catenane by cyclodimerization of a difunctional precursor. The circles represent the templating transition metal, and the triangles the terminal diynes.

striking property of this family of catenane-type ligands is their ability to stabilize low oxidation states of several transition metals. Comparison of the catenanes with their acyclic analogues shows in several cases a strong contribution of the topological factor of the catenane to such stabilization effect. Whereas the reduction potential values of $[M.Cat]^{n+}$ and $[M(dap)_2]^{n+}$ are in several instances very close, the kinetic stability of the reduced catenane with respect to dissociation or reoxidation is always noticeably more pronounced than that of the corresponding open-chain complex.

8.2.5 Dimetallic [3]Catenates

Synthesis

[3]Catenates have been prepared in good yield by double acetylenic oxidative coupling from a terminal diyne threaded into a preformed chelating ring according to Figure 7 [46]. The precursor used, the reaction conditions, and the [3]catenane thus obtained are represented in Figure 8.

The dicopper complex $CuCu.10^{2+}$ made of two peripheral 30-membered rings separately interlocked to a bis-diacetylenic 44-membered central cycle could be fully characterized by extensive NMR and crystallographic studies [47]. These studies provided clear evidence that the molecular shape of $CuCu.10^{2+}$ was approximately the same in the CH_2Cl_2 solution and in the solid state. Indeed, the molecule does not present an extended geometry (as the diagram in Figure 8 would suggest), but rather it is completely curled up so as to allow close contact between various parts of the two copper(I) complex subunits (Figure 9).

The [3]catenane $CuCu.10^{2+}$ could be fully demetalated with excess potassium cyanide, affording the free ligand **10** which could be later easily remetalated giving thus access to the following homodinuclear [3]catenates: $AgAg.10^{2+}$, $ZnZn.10^{4+}$, $CoCo.10^{4+}$, and $NiNi.10^{4+}$.

Figure 8. Synthesis of the [3]catenate **CuCu.10²⁺**.

Homodinuclear [3]catenates

The strong electronic interactions between the two metal centers were not expected, since the 8.5 Å Cu...Cu distance, found in the X-ray structure of **CuCu.10²⁺**, is rather long. Nevertheless, since the space between the metal centers is filled up with stacking aromatic nuclei in the folded conformation, some interesting effects (of one complex subunit on the properties of the other) could be observed. The electronic properties of the various symmetrical dimetallic [3]catenates were studied and

compared to those previously obtained for the corresponding [2]catenates [28] designed by **M.5ⁿ⁺**.

The electrochemical data collected in Table 4 show at first that most of the [3]catenates studied undergo highly reversible electroreductive processes. A typical example is that of **CoCo.10⁴⁺**, for which the cyclic voltammogram is represented in Figure 10.

The $\Delta E_{[3]-[2]}$ values given in Table 4 reflect the greater tendency of the [3]catenates to be reduced as compared to their monometallic analogues, although the electronic properties (σ and π electron-donating and -accepting character) of the individual coordinating species are identical for both systems. A possible explanation is that in [3]catenates the reduced species is slightly stabilized by electrostatic interaction with the positively charged second subcomplex. This stabilizing charge effect may occur by direct metal-to-metal or through-space interactions. Given the large metal-to-metal distance (8.5 Å) found in the structure of **CuCu.10²⁺**, and assuming that the metals cannot be much closer in the other complexes due to steric repulsion within the organic skeleton of the ligand, it is reasonable to assume that this stabilizing charge effect occurs predominantly via the π system of the ligands.

Figure 10. Cyclic voltammogram of **CoCo.10⁴⁺** (4.2×10^{-4} M) in $\text{CH}_3\text{CN}-(\text{nC}_4\text{H}_9)_4\text{N}^+.\text{BF}_4^-$ 0.1 M (Pt, scan rate 100 mV s^{-1} , E versus SCE).

Interestingly, **ZnZn.10⁴⁺** and **Zn.5²⁺** are reduced at almost the same potential. This indicates that the [3]catenate is less curled up in this case due to strong electrostatic repulsion between the two hard dicationic Zn^{II} centers. ^1H NMR data fully corroborate this hypothetical more extended conformation of **ZnZn.10⁴⁺**.

Heterodinuclear [3]catenates

The controlled demetallation of **CuCu.10²⁺** by potassium cyanide at room temperature afforded the mononuclear complex **Cu.10¹⁺** containing a vacant site ready for coordination. Addition of the appropriate salt (AgBF_4 or $\text{Co}(\text{BF}_4)_2$) to **Cu.10¹⁺** leads to the heterodinuclear [3]catenates **CuAg.10²⁺** and **CuCo.10³⁺** for which the specific electrochemical properties [48] were studied and compared to those of their monometallic analogues, namely **M.5ⁿ⁺** (Table 5).

As expected, the redox potential of the $\text{Cu}^{2+}/\text{Cu}^+$ couple is slightly shifted towards anodic values in **CuAg.10²⁺** as compared to **Cu.5⁺**. This effect is even more pronounced in **CuCo.10³⁺**: the copper(II) state is significantly more difficult to electro-generate than for the mono-nuclear species **Cu.5⁺**. The positive shift of the $\text{Cu}^{2+}/\text{Cu}^+$ redox potential in di-metallic species as compared to **Cu.5⁺** shows that the two metal complex subunits of the [3]catenates do interact. This may reflect an

Table 5. Electrochemical properties of the heterodinuclear complexes **CuM.10ⁿ⁺**

Compound	Redox couple	E _{red} (V) ^a

electrostatic interaction between the cationic metal centers (through-space or via the stacking π -system). As in **CuCu.10²⁺** the oxidation reaction of copper(I) to the di-valent state is made more difficult by the vicinity of an additional positive charge. The rise in copper(I) oxidation potential ($\Delta E_{\text{Cu}^{2+}/\text{Cu}^+}$) from **Cu.5⁺** to **CuM.10ⁿ⁺** represents the extent of electrochemical stabilization of the low valence state Cu^I by the second metal. As foreseen, it increases with the positive charge of M (Table 6).

The large value found for Co²⁺ (+0.22 V) is a good indication for a folded up conformation of **CuCo.10³⁺** which allows a strong electrostatic repulsion between Cu²⁺ and Co²⁺. In an extended geometry, the two metal centers would be too far away to interact, as was the case in the less-folded tetracationic species **ZnZn.10⁴⁺**. The electrostatic interaction between the two positively charged metals of the [3]catenates **CuM.10ⁿ⁺** is also reflected by the reduction potentials of the M-containing parts. The M-containing subunit is easier to reduce as compared to **M.5^{(n−1)+}** due to the proximity of the Cu⁺ center in the curled up [3]catenates **CuAg.10²⁺** and **CuCo.10³⁺**. Table 5 shows that this Cu⁺ effect is roughly the same on Ag⁺ or Co²⁺ (+0.22 and 0.24 V for $\Delta E_{\text{Ag}^+/\text{Ag}^0}$, and $\Delta E_{\text{Co}^{2+}/\text{Co}^+}$, respectively).

Figure 11. Dicopper(I) trefoil knots and related acyclic monocopper(I) complex.

8.2.6 Dimetallic Molecular Trefoil Knots

The early “methylenic” bridged symmetrical dicopper knots

The electrochemical properties of the dicopper knots represented in Figure 11 were compared to that of the simply entwined copper complex **Cu.(11)₂⁺**, which should have identical electronic properties so that any difference between the latter mono-copper complex and the dicopper knotted ones can be attributed both to structural (i.e., geometric) and topological factors and, in particular, to the geometry of the copper(I) coordination polyhedra and the accessibility to the metal centers [49].

Cyclic voltammetry measurements (Table 7) showed clearly that the acyclic complex **Cu.(11)₂⁺** was the easiest one to oxidize, and that in the dinuclear knots **CuCu.12²⁺** and **CuCu.13²⁺**, the two copper(I) centers behave independently of one another. The redox potential of **CuCu.12²⁺** appears surprisingly high (140 mV higher than the redox potential of **CuCu.13²⁺**), which indicates that the 84-

Table 7. Oxidation potentials of copper(I) mono- and dinuclear knots complexes^a

	Cu(11)₂⁺	CuCu.12²⁺	CuCu.13²⁺
E^0 (V)	0.42	0.75	0.61

^aCyclic voltammetry in CH₃CN versus SCE, LiClO₄ (0.1 M) as supporting electrolyte, oxidation on Pt, scan rate 100 mV/s.

membered knotted cycle is highly constraining and allows only limited freedom for the copper(I) centers to change their geometry. This observation is in good accordance with the structure of the complex [50]: the $-(\text{CH}_2)_6-$ linker is sufficiently long to form a well-twisted central double helix, thus ensuring efficient shielding of the metal centers. On the other hand, the pentaethylene glycol link is too short for the molecule to easily distort. The rigidity thus obtained “freezes” the copper centers in a pseudotetrahedral geometry, making any deformation of their coordination polyhedra towards a square planar geometry extremely difficult.

These results strongly suggest that the electrochemical properties of the knots are not governed by the topological factors alone. They are obviously also very sensitive to structural parameters which become prevailing when switching from the aliphatic flexible spacers between two phenanthroline units to the more rigid 1,3-phenylene spacer in knot **CuCu.14**²⁺.

The *meta*-phenylene bridged knots

Knot **CuCu.14**²⁺ in which the two phenanthrolines are connected by a 1,3-phenylene bridge could be characterized both by ¹H NMR and crystallographic studies as being a highly rigid and compact edifice with a much shorter Cu...Cu distance than in the previously synthesized knots (4.76 Å, cf. 6.3 or 7.0 Å) [51]. Due to this very short Cu...Cu distance, knot **CuCu.14**²⁺ undergoes two very distinct oxidation processes. The redox potentials of the Cu²⁺/Cu⁺ couples measured in CH₃CN against the saturated calomel electrode (SCE), all reversible ($\Delta E_p = 60$ mV), appear at $E^\circ = +0.68$ V for **CuCu.14**^{3+/2+} and at $E^\circ = +0.92$ V for **CuCu.14**^{4+/3+}. The surprisingly high value found for **CuCu.14**^{4+/3+} indicates a strong electronic interaction between the two copper centers. The presence of divalent copper(II) located close to the copper(I) undergoing the redox reaction renders the oxidation of this second metal difficult, and thus shifts the Cu²⁺/Cu⁺ redox potential substantially towards anodic values. Furthermore, the large difference of redox potential values for the two couples Cu²⁺Cu²⁺/Cu²⁺Cu⁺ (+0.92 V) and Cu²⁺Cu⁺/Cu⁺Cu⁺ (+0.68 V), $\Delta E = 0.24$ V, is remarkable. It corresponds to a large comproportionation constant K_c , for the following reaction:

K_c being larger than 10^4 , it should be possible to isolate and study the mixed-valence state **CuCu.14**³⁺.

Another feature also strongly related to the compactness of the *m*-phenylene bridged knot is its extreme kinetic inertness in the cyanide demetalation process, which could be shown to imply two rate-limiting steps that are well resolved in time (Figure 12) [52].

If the removal of both copper(I) ions requires heating for 24 h under reflux in acetonitrile and a 1000-fold excess of potassium cyanide, by contrast, less drastic conditions afford quantitatively the stable, isolable, singly demetalated species **Cu.14**¹⁺ which, because of its free coordination site, seemed an ideal precursor for the synthesis of nonsymmetrical knotted complexes. Indeed, simple addition of the

Figure 12. Representation of the two steps in the demetalation of the dicopper(I) knot CuCu.14^{2+} .

appropriate metal salt to Cu.14^{1+} afforded in quantitative yield the heterodinuclear complexes CuZn.14^{3+} and CuAg.14^{2+} . Both of these heterodinuclear complexes undergo only one oxidation process: $E^\circ = +0.69$ V for $\text{CuAg.14}^{3+/2+}$ and $E^\circ = +0.90$ V for $\text{CuZn.14}^{4+/3+}$.

The $\text{CuCu.14}^{3+/2+}$ and $\text{CuAg.14}^{3+/2+}$ reduction potentials are very similar to those found for the other copper complexes containing entwined or interlocked ligands [28]. By contrast, the $\text{CuZn.14}^{4+/3+}$ reduction potential is very high and comparable to the value found for the $\text{CuCu.14}^{4+/3+}$ complex. Here again, this value reflects the strong electron-withdrawing influence of a divalent metal atom located close to the copper center undergoing the redox reaction. As expected, the presence of a positively charged species substantially destabilizes the divalent state of the copper center.

All the electrochemical data obtained for the phenylene bridged knots clearly show that the presence of a “conducting” spacer inside a narrow rigid central helical core leads to electrochemical properties that are noticeably different from those of knotted complexes in which the two metal-based components are linked by nonconducting $-(\text{CH}_2)_n-$ spacers [49].

8.2.7 A Mononuclear Hexacoordinated Ruthenium Bis-Terpyridine [2]Catenate

The catenanes and knots described so far, originating from the use of 2,9-diaryl-1,10-phenanthroline in combination with copper(I) as assembling and templating centre, contain all tetrahedral coordination sites that are particularly well suited to low oxidation states with various transition metals. In order to prepare interlocking ring ligands able to complex metals in high oxidation states, 6-coordinate systems are preferable. This requirement led to the synthesis of a bis(terpyridine)ruthenium(II) catenate following the three-dimensional template route described in Figure 13 [53].

Figure 13. Template synthesis of the ruthenium bis-terpyridine catenate **Ru.16²⁺**.

Such multistep synthesis, the key step of which involved the reaction of the ruthenium(II) complex of 5,5''-bis(4-hydroxyphenyl)terpyridine (**Ru.15²⁺**) with two equivalents of the diiodo derivative of hexaethylene glycol afforded the target catenate **Ru.16²⁺**. The electrochemical data obtained for **Ru.16²⁺** and its open-chain precursor **Ru.15²⁺** are summarized in Table 8, along with those of $[\text{Ru}(\text{tpy})_2]^{2+}$ ($\text{tpy} = 2,2':6',2''\text{-terpyridine}$) given for comparison.

The oxidation potentials of the Ru^{II} ions in the catenate complex and in **Ru.15²⁺** are both slightly higher than in $[\text{Ru}(\text{tpy})_2]^{2+}$, which is simply an effect of substituting the terpyridine. More important is the fact that the oxidation potentials of **Ru.16²⁺** and **Ru.15²⁺** are the same, which indicates that closure of the two rings to form the catenate does not have a large effect on the geometry around the ruthenium ion. The two ligand-based reductions of **Ru.16²⁺** and **Ru.15²⁺** appear significantly easier than for $[\text{Ru}(\text{tpy})_2]^{2+}$. This was expected due to the more highly conjugated nature of the ligands; again, however, they are approximately the same. These results suggest that the Ru-N_6 coordination environment is very similar for all three complexes, and hence that no significant change in the geometry at the metal ion has arisen as a result of closing the macrocyclic rings. It might be expected that if the linker chain were shorter, closure of the rings could pinch the terpyridyl moieties enough to promote a noticeable change in the coordination environment of the ruthenium ion.

8.3 Photophysical Properties of Catenates and Knots

8.3.1 Introduction

The pioneering work of McMillin and colleagues [54] has shown that the $[\text{Cu}(\text{phen})_2]^+$ -type motif (phen = 1,10-phenanthroline) is very interesting from the photophysical point of view, provided that the phenanthroline chelating units bear substituents, typically in the 2,9 and/or 4,7 positions [54e–f]. Only in these cases, in fact, a relatively long-lived, luminescent metal-to-ligand-charge-transfer (MLCT) excited state is made available, whereas for plain $[\text{Cu}(\text{phen})_2]^+$ such an excited state is short-lived and not luminescent under any condition. This behavior is a consequence of the structure of the excited complex, where a formally Cu^{II} ion is formed following the excitation in the MLCT manifold, thus favoring a strong flattening towards a square planar geometry in place of the starting pseudotetrahedral arrangement, preferred by Cu^{I} . The strongly distorted excited molecule tends to form pentacoordinated exciplexes with the counteranion and/or the solvent molecules [54d,g], which are deactivated to the ground state via nonradiative paths. As a consequence, any factor which can limit such deactivation process is able to increase the luminescence quantum yield and excited state lifetime of $[\text{Cu}(\text{phen})_2]^+$ -type complexes. Practically, one can act on three factors: (i) solvent nature; (ii) chemical nature, size, and number of the substituents; and (iii) type of counteranion. In order to maximize the luminescence performances, poor donor solvents, numerous [54n] and/or cumbersome substituents (which physically prevent the undesired nucleophilic attack), and poor donor counteranions must be utilized. As a matter of fact, most of the photophysical investigations on copper phenanthrolines are reported in CH_2CH_2 , phenyl substituents are usually placed on the chelating unit, and BF_4^- or PF_6^- counteranions are employed.

Importantly, the MLCT nature of the lowest excited state of $[\text{Cu}(\text{phen})_2]^+$ -type complexes has been unambiguously demonstrated by several techniques, including resonance Raman [55] and transient absorption [56] spectroscopy.

Finally, it must be pointed out that a great deal of work was published on related metal assembled compounds such as linear or circular helicates [57], cages [58], and rack-type complexes [59]. However, since little or no discussion related to charge-transfer spectroscopy or photoinduced electron transfer was reported, they will not be presented here.

8.3.2 Metallo-[2]catenates

The first report on the photophysical properties of metal catenates dates back to 1989 [54h], when a comparison between a 27- (**Cu.4**⁺; Figure 2) and 30-membered (**Cu.5**⁺; Figure 14) ring catenates was reported.

The absorption spectra of the two complexes are significantly different both at 298 and 90 K, and the emission band of the smaller size catenate is blue-shifted relative to **Cu.5**⁺ (715 versus 730 nm). Interestingly, the lifetime of **Cu.4**⁺ in

Figure 14. The [2]catenand **5** and its catenates **M.5ⁿ⁺** ($M = \text{Li}^+, \text{H}^+, \text{Ag}^+, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Zn}^{2+}, \text{Cd}^{2+}, \text{Pd}^{2+}$). The line connecting the oxygen atoms of the closing chains represent $-(\text{CH}_2)_2-$ groups. The Pd^{II} catenate shows a cyclometallate structure, as represented in Figure 2 (**Pd(5-H)⁺**).

CH_2Cl_2 deaerated solution (280 ns) is longer than that of **Cu.5⁺** (190 ns). This is a consequence of the more rigid structure of the smaller-size complex that disfavors excited state distortions, and has been well correlated with electrochemical data that show a remarkable 124-mV anodic shift in passing from the 30- to the 27-membered ring (see Section 8.2.3).

Some years later, the investigation on **Cu.5⁺** was extended to the corresponding **M.Catⁿ⁺** catenates ($M = \text{Li}^+, \text{H}^+, \text{Ag}^+, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Zn}^{2+}, \text{Pd}^{2+}, \text{Cd}^{2+}$) [60] (Figure 14). The absorption spectra of all these compounds in CH_2Cl_2 solution are reported in Ref. [60]. The ligand-centered (LC) $\pi\pi^*$ transitions in the UV spectral region (220–400 nm, ϵ_{max} of the order of $10^4 \text{ M}^{-1} \text{ cm}^{-1}$), are strongly affected by metal complexation, and a certain similarity is found for catenates bearing ions with the same electrical charge. The low-energy absorption bands above 400 nm are strongly dependent on the electronic configuration of the complexing ion; as a consequence, a remarkably different spectral shape is observed from case to case. Closed shell (d^{10}) divalent ions such as Zn^{2+} and Cd^{2+} bring about a broadening of the ligand-centered bands toward the visible spectral region. This is due to the sizeable charge transfer character of the ligand-centered transitions in the di-*n*isylphenanthroline-type (dap) ligands [61], that are thus lowered in energy by the electrostatic effect of the divalent complexing ion. Such an effect is not found for monovalent ions like Ag^+ (d^{10}) and Li^+ ; the spectra of **Ag.5⁺** and **Li.5⁺** do not exhibit any broadening above 400 nm. By contrast, the complexation with H^+ causes a spectral widening towards the red spectral region, even more dramatic than in the case of Zn^{2+} and Cd^{2+} , probably due to the very high charge density of the proton.

For Cu^+ (d^{10}) and open-shell metal ions, the absorption spectra in the visible spectral range are totally different, and weak bands (ϵ of the order of $10^3 \text{ M}^{-1} \text{ cm}^{-1}$) are found up to 600–700 nm. **Cu.5⁺** exhibits the expected wide MLCT absorption (see above), whereas the bands observed for Ni^{2+} (d^8) and Co^{2+} (d^7) are assigned to metal-centered (MC) or ligand-to-metal-charge-transfer (LMCT) transitions. Finally, the Pd^{2+} (d^8) catenate has to be considered a special case since it is actually a

Figure 15. Luminescence spectra of some $M.5^+$ catenates in CH_2Cl_2 . From left- to right-hand-side, maxima correspond to $M = Li^+, Zn^{2+}, Ag^+, H^+, Pd^{2+}, Cu^+$ (alternate full and dashed line, for the sake of clarity). The spectra of the silver(I) and palladium(II) catenates are recorded at 77 K, all the others at 298 K.

cyclometallate [62], and for such Pd^{2+} complexes MC and MLCT excited configurations may lie very close in energy, and contribute to the observed spectra [62]. However, it must be pointed out that a localized molecular orbital approach for cyclometallated compounds can only be used as a first approximation, since a large degree of covalency in the metal–ligand bond is expected.

The wide tuning of the electronic properties of [2]catenates, as observed from electrochemistry and UV-visible absorption, causes a nice modulation of the luminescence properties in CH_2Cl_2 solution. On changing the metal ion, the luminescence bands of this catenate family are tuned throughout the whole visible spectral region [60] (Figure 15). The luminescence data at 298 and 77 K in CH_2Cl_2 are reported in Table 9.

In detail, the luminescence bands of the $Li^+, Cd^{2+}, Zn^{2+}, H^+$ catenates $M.5^+$ are of LC ($\pi\pi^*$) character (fluorescence and phosphorescence); for $Ag.5^+$ only the 77 K LC phosphorescence is observed due to the rapid singlet–triplet intersystem crossing induced by the heavy metal ion; the luminescence band shown (only) at 77 K by $Pd.5^+$ is difficult to attribute (see above), but a substantial MLCT character is indicated by the spectral red-shift and shorter lifetime compared to, for instance, $Ag.5^+$; finally, the $Cu.5^+$ shows the typical MLCT band (see above). No luminescence is observed for $Ni.5^+$ and $Co.5^+$ owing to the presence of low-lying non-

emissive MC excited states which offer a rapid, radiationless decay path to the ligand-centered $\pi\pi^*$ levels.

8.3.3 Multicomponent Metallo-[3]catenates

The wide tunability in the redox and electronic properties of [2]catenates by varying the complexing ion suggests that intercomponent photoinduced energy or electron transfer processes could occur in thoroughly designed polynuclear catenates containing such chromophoric units [63–64] (Figure 16).

The absorption spectra of the free ligand **10** and its mono- and dinuclear complexes **Cu.10⁺**, **CuCu.10²⁺**, **CuAg.10²⁺**, **CuZn.10³⁺**, **CuZn.10³⁺**, are reported in Ref. [64]; these spectra are well-matched with the sum of the spectra of the two chromophoric (**M.5ⁿ⁺**-type) component units. The luminescence properties of all [3]catenates at 298 and 77 K in CH₂Cl₂ are reported in Table 10.

The emission behavior of the free ligand **10** and of the homodinuclear **CuCu.10²⁺** catenate is quite comparable to that of the simpler corresponding [2]catenand **2** and [2]catenate **Cu.5ⁿ⁺**. By contrast, a dramatic luminescence quenching of one of the two moieties is observed in all the heterodinuclear compounds.

Cu.10⁺ is made of a catenand (metal-free) and a catenate (metal-complexed) moiety. Selective excitation of the Cu^I-complexed moiety in the visible spectral re-

Figure 16. The [3]catenand **10** and its mononuclear (**Cu.10⁺**), and dinuclear (**CuM.10ⁿ⁺**) metal-locatenates ($M = \text{Cu}^+, \text{Ag}^+, \text{Co}^{2+}, \text{Zn}^{2+}$).

gion gives rise to a MLCT emission band, whose quantum yield is identical to that of the parent **Cu.5⁺** and twice that of **CuCu.10²⁺**. This shows clearly that in the dinuclear complex the coordination geometry is modified relative to the mononuclear species, due to the reciprocal steric interactions of the two moieties which are quite close to each other as observed in the solid state [47]. Excitation in the 320-nm LC band gives a blue-shifted, dramatically quenched fluorescence band. The corresponding lifetime, which is 2.4 ns in the reference compound, is shortened to 40 ps. In principle, such quenching can occur by either energy or electron transfer, but excitation spectra clearly show that energy transfer is not the predominant process. Indeed, electron transfer from the Cu^+ ion of the catenand moiety to the LC state of the dap fragment of the catenand moiety is thermodynamically allowed ($\Delta G = -0.43$ eV). A similar behavior was more recently observed [18] for the [2]catenand **Cu.6⁺** made of two moieties, i.e., a Cu.Cat-type and a free phen-type fragment; also in this case a very rapid luminescence quenching of the uncomplexed subunit is observed ($k_q = 1.6 \times 10^{10} \text{ s}^{-1}$).

CuAg.10²⁺ exhibits only the MLCT emission of the Cu-based moiety both at 298 and at 77 K, at any excitation wavelength. This shows that population of the excited LC levels of the Ag-based moiety, is followed by energy transfer to the Cu^I-complexed moiety, as confirmed by excitation spectra.

^aValues corrected for the photomultiplier response.^bLigand-centered (LC) fluorescence.^cLC phosphorescence.^dIncluding some contribution from impurities of **10**.^eNot available value under these conditions; no LC phosphorescence was detected.^fLuminescence from the lowest metal-to-ligand-charge-transfer (MLCT) excited state of the Cu(I)-complexed moiety.^gImpossible to evaluate because the MLCT emission overlaps with a higher energy luminescence band (see text).

A similar behavior is found for **CuZn.10³⁺**, where the Cu-based moiety shows luminescence properties quite similar to those of **CuAg.10²⁺** and **CuCu.10²⁺**; instead, the Zn-based moiety is quenched, with $k_{\text{q}} = 1.1 \times 10^{10} \text{ s}^{-1}$ at 298 K. Quite peculiarly, for this [3]catenate a broad emission band with maximum at 560 nm is detected, that can hardly be assigned to an impurity of some sort [64]. Tentatively, it was attributed to an intercomponent CT interaction which could play a role in the quenching of the LC fluorescence in **CuZn.10³⁺**.

Finally, the **CuCo.10³⁺** catenate does not luminesce under any condition, showing that the potentially luminescent MLCT level of the Cu-complexed moiety is quenched by the Co-based one. A possible quenching mechanism is energy transfer, since the d⁷ Co²⁺ metal ion has low-energy d-d levels ($< 10\,000 \text{ cm}^{-1}$) [65], but also electron transfer is thermodynamically allowed ($\Delta G = -0.54 \text{ eV}$).

A comprehensive view of the intercomponent processes taking place in this family of [3]catenates is illustrated schematically in Figure 17.

8.3.4 Proton [2]- and [3]Catenates

In CH₂Cl₂ solution, 1,10-phenanthroline and its derivatives can be protonated on the nitrogen atoms, and the reaction can be followed by absorption and luminescence spectroscopy [61].

Figure 17. Direction of photoinduced processes observed in the [3]catenates CuM.10^{n+} .

On addition of increasing amounts of acid, the absorption spectra of phenanthrolines undergo strong changes and a single family of isosbestic points is found; in parallel, the intensity of the starting emission band decreases and a new, red-shifted band emerges [61]. These results clearly demonstrate that a single protonation reaction takes place and prompted us to investigate by UV-visible spectroscopy the protonation of the catenands and catenates having one or more protonable sites, i.e., **5** [60], **10** [66], and Cu.10^+ [66].

For the [2]catenand **5**, two clearly distinct protonation reactions are found, and it was demonstrated unambiguously that both protonated forms have a catenate structure [60, 67], i.e., the two dap fragments are arranged in an entwined structure identical to that involved for metal catenates. The driving force for this unexpected behavior is likely to be the $\pi\pi^*$ electronic donor–acceptor interactions between phenanthroline and anisyl fragments that can be established only in the catenate-type arrangement, and not in a open form. The luminescence properties of **5** and its protonated forms H.5^+ and $(\text{H}_2)\text{.5}^+$ are reported in Table 9.

Also in the case of Cu.10^+ , where a [2]catenand-type moiety is present, a two-step protonation reaction occurs, but in this case the luminescence of such moiety is quenched by the Cu-based one [66]. Unfortunately, it is not possible to determine the quenching rate and mechanism for a variety of reasons, including: (i) the instability of the protonated forms under laser irradiation in CH_2Cl_2 [56]; (ii) the lack of electrochemical potentials of the protonated forms; and (iii) the weakness of the MLCT emission band of the Cu-based moiety, which is partially masked by the tail of the emission of the protonated subunit, albeit quenched. However, the energy transfer mechanism is thermodynamically allowed and probably active.

For the [3]catenand **10**, four successive protonation reactions are observed via absorption and luminescence spectroscopy [66]. Interestingly, after the first protonation step a nonsymmetrical proton catenate is formed, where one moiety is protonated and the other is free. In this case, luminescence quenching of the unprotonated subunit by the protonated one is found, most likely by energy transfer.

Figure 18. The [2]catenates **RuM.8ⁿ⁺** ($M = \text{Ag}^+$, Cu^+ , Zn^{2+} , or nothing).

8.3.5 Multicomponent Metallo-[2]catenanes

The complexes **RuCu.8³⁺** (Figure 18) represent a special case of [2]catenates where one of the two interlocked rings is closed via coordinative bonds. From the photophysical point of view, such compounds offer the possibility of studying dinuclear complexes where the two subunits have different coordination geometry, i.e., octahedral ($[\text{Ru}(\text{tpy})_2]^{2+}$ -type) and tetrahedral ($[\text{M}(\text{phen})_2]^+$ -type) [68]. The $[\text{Ru}(\text{tpy})_2]^{2+}$ -type unit has been extensively investigated [69] and also largely employed in the construction of rod-like polynuclear complexes [70]. The absorption spectra of such Ru^{II} -complexes exhibit intense LC $\pi\pi^*$ absorption bands in the UV and weaker MLCT features in the visible spectral region. The lowest MLCT excited state of $[\text{Ru}(\text{tpy})_2]^{2+}$ is short-lived ($\tau < 1$ ns) and not luminescent at room temperature (unlike the $[\text{Ru}(\text{bpy})_3]^{2+}$ -type compounds), whereas at 77 K a strong luminescence band ($\tau = 10.6 \mu\text{s}$) [69] is observed.

The absorption spectra of the **RuM.8ⁿ⁺** catenates [68] correspond to the sum of the spectra of the pertinent model compounds, as observed for the [3]catenates described in Section 8.3.3. This indicates that ground-state intercomponent interactions are weak, and is consistent with the fact that the two moieties are linked by aliphatic chains. The luminescence properties are reported in Table 11 and compared to those of the proper model compounds; they show that in all cases there is always luminescence quenching of one of the two moieties, suggesting that strong intercomponent excited state interactions occur.

For **Ru.8²⁺** and **RuZn.8³⁺**, at 298 K, the fluorescence of the lowest ligand-centered singlet excited state (^1LC) of the uncomplexed (**5**-type) and complexed (**Zn.5²⁺**-type) moieties is strongly quenched by the $[\text{Ru}(\text{tpy})_2]^{2+}$ -based unit (Table 11); the quenching rate constants result to be $> 5 \times 10^{10} \text{ s}^{-1}$. From the electrochemical results [68] one can argue that for **Ru.8²⁺**, both oxidative and reductive electron transfer processes are not thermodynamically allowed upon excitation of the lowest ligand-centered level of the free moiety. Instead, energy transfer to the lowest MLCT level of the other subunit is energetically allowed, and can account for the observed quenching process. In the case of **RuZn.8⁴⁺**, oxidative electron transfer quenching of the Ru^{II} center is thermodynamically allowed, but only upon excitation of the **Zn.5²⁺**-type moiety, so this could perhaps contribute to the quenching process of ^1LC at 298 K. At 77 K, for both **Ru.8²⁺** and **RuZn.8⁴⁺**, complete quenching of the ^1LC and ^3LC (lowest ligand-centered triplet excited state) levels of the “phen-type” moieties is observed and it can be accounted for by

an energy transfer to the MLCT levels of the [Ru(tpy)₂]²⁺ fragment, which turns out to be sensitized in the excitation spectra.

For **RuAg.8³⁺**, at 298 K oxidative electron transfer quenching of the Ru^{II} center is thermodynamically allowed (regardless of the excited component) so that a contribution of such mechanism to the observed complete fluorescence quenching of the Ag^I-complexed moiety cannot be excluded, probably in competition with a fast ¹LC → ³LC intersystem crossing, in analogy with what was observed for the mononuclear **Ag.5⁺**. In rigid matrix at 77 K, sensitization of the MLCT Ru^{II}-based emission is observed; therefore, the lack of fluorescence and phosphorescence is clearly related to an energy transfer process to the MLCT level of the [Ru(tpy)₂]²⁺ moiety.

In the case of **RuCu.8³⁺**, the picture is different because the lowest excited state is no longer the MLCT level of the [Ru(tpy)₂]²⁺ moiety, but that of the [Cu(phen)₂]²⁺-type. The excitation spectra (taken at 720 nm) show that there is no appreciable contribution from the [Ru(tpy)₂]²⁺-based absorption bands in the visi-

Figure 19. Direction of photoinduced processes observed in the [2]catenates **RuM.8ⁿ⁺**.

ble spectral region, because the very fast internal deactivation cannot compete with energy transfer. In contrast, at 77 K, the [Ru(tpy)₂]²⁺-based emission is dramatically quenched, with a rate constant of $3 \times 10^8 \text{ s}^{-1}$; unfortunately the excitation spectrum read on the Cu^I-based emission could not be recorded, due to the signal weakness. Nevertheless, the observed quenching can be assigned to an energy transfer mechanism. In fact, at 298 K, the electron transfer (corresponding to the reduction and oxidation of the Ru^{II} and of the Cu^I metal center, respectively) is exergonic by only 0.17 eV—a value most likely not sufficient to allow for electron transfer in a 77 K rigid matrix.

In conclusion, for the **RuM.8ⁿ⁺** [2]catenates family, photoinduced intercomponent energy and/or electron transfer processes are evidenced. The direction of such processes can be tuned upon a suitable choice of the metal ion complexing the [M(phen)₂]ⁿ⁺-type coordination center, according to the schematic representation of Figure 19.

8.3.6 Homo- and Heterodinuclear Knots

The dicopper(I) trefoil knots **CuCu.12²⁺**, **CuCu.13²⁺**, **CuCu.17²⁺**, and **CuCu.18²⁺**, are shown in Figure 20. From the structural point of view they have the same coordinating ligands, but along the series the two coordination cores are linked by fragments of different length, i.e., the internal polymethylene chain (Z) and the external polyethyleneoxy unit (X) used in the final cyclization synthetic step. Therefore such complexes provide a unique opportunity to study whether slight structural modification of the coordination environment, as those induced by different Z or X chains, can lead to some changes in the UV-visible spectroscopic properties [49]. Some selected photophysical properties are reported in Table 12.

The absorption bands of the knots in the UV region are, as for the catenanes, mainly due to ligand-centered $\pi\pi^*$ transitions, and are only slightly affected by the

Figure 20. The dicopper(I) knots made of two identical chromophoric centers linked by two threads (X and Z), each of which can be of different length.

actual structure of each knot. More pronounced variations are found for the MLCT transitions in the visible spectral region, where the molar absorption coefficients at the absorption maxima are identical for all the knots, but the spectral shapes have remarkable differences [49]. This shows that the three groups of MLCT absorption bands evidenced for the $[\text{Cu}(\text{phen})_2]^{n+}$ -type complexes (and denominated I, II, and III) [54i] are, to a different extent, affected by the length of the Z and X bridges. For instance **CuCu.17²⁺**, where the Z connection is the shortest, exhibits a peculiar broadening on the red side of the lower energy bands I and II.

Figure 21. The homo- and hetero-dinuclear knots **CuM.14ⁿ⁺** with the phenylene interchromophoric spacer.

All the knots exhibit MLCT luminescence bands at 298 and 77 K, but the luminescence properties are not identical along the series. The most interesting result is that the luminescence bands of **CuCu.12²⁺** and **CuCu.18²⁺** are blue-shifted, more intense, and longer-lived compared to those of the other knots and also of the proper mononuclear model compound [49]. They also display larger radiative (k_r) and smaller nonradiative (k_{nr}) rate constants compared to those of the other knots. This suggests that they possess a more symmetric and rigid structure than the other knots, which tends to disfavor the nonradiative deactivation of the lowest excited state via pentacoordinated exciplexes (see above). Importantly, this fits well with electrochemical results, which show that **CuCu.12²⁺** has a surprisingly high oxidation potential (+0.75 V versus SCE) 140 mV higher, for instance, than that of **CuCu.13²⁺** (see Section 8.2.6).

In summary, for this family of dicopper(I) dinuclear knots the photophysical and electrochemical properties allow them to be ordered in a series where the two extremes are **CuCu.12²⁺** and **CuCu.17²⁺**, the former being the most rigid and the one in which Cu^I is best shielded. This shows that the length of the shorter Z connection plays an important role in determining the fine structure of the geometric arrangement.

The possibility of observing photoinduced intercomponent processes in hetero-dinuclear knotted complexes was made possible with the knots bearing a phenylene unit, as interchromophoric spacer [52b] (Figure 21). In fact, in this case the synthetic yield of the parent dicopper complex is high enough to allow further decomplexation–recomplexation steps, as required.

The photophysical properties of the complexes thus obtained (**Cu.14⁺**, **CuCu.14²⁺**, **CuAg.14²⁺**, **CuZn.14³⁺**) are reported in Ref. [52b]. The absorption spectra exhibit the usual LC $\pi\pi^*$ bands in the UV, and the weaker MLCT bands in the visible spectral region. The spectra are rather different from those of the above homodinuclear series, and this is a consequence of the fact that two phenyl substituents are placed on the phenanthroline rings, whereas in the previous case there is one phenyl and one alkyl residue. This is expected to strongly affect the electronic MLCT transitions, also as a consequence of a slightly different coordination geometry.

Some luminescence data are reported in Table 13. Only one emission band is observed above 700 nm, assigned to the lowest MLCT excited state, irrespective of the excitation wavelength. The good matching between absorption and excitation

Table 13. Luminescence data for the **CuM.14ⁿ⁺** knots in CH₂Cl₂^a

spectra throughout the UV/visible spectral region shows that, for any knot, complete conversion occurs of all the upper lying excited states to the lowest emitting MLCT level. This implies that in the heterodinuclear compounds intercomponent energy transfer towards the Cu-based moiety takes place from the other chromophoric center. In the case of **CuZn.14³⁺**, an emission band at 950 nm (attributed to the lowest MLCT excited state of the Cu-based unit) is detected. Such dramatic shift is attributed to a strong electrostatic effect of the nearby divalent Zn²⁺ ion on the MLCT transitions. Such an effect is not observed for the monovalent Ag⁺ ion in **CuAg.14²⁺**, and also in the previously described [3]catenate **CuZn.10³⁺**, where the two moieties were electronically insulated and further apart. In other words, the phenylene spacer leads to spectroscopic (and electrochemical) properties quite different from those of homonuclear knotted complexes in which the two chromophoric units are linked by insulating polymethylene chains. The comparison with heterodinuclear [3]catenates shows the strong conducting electronic character of such an aromatic spacer.

8.3.7 Quenching by Dioxygen

For all the above-reported Cu^I catenates and knots, on excitation of the MLCT absorption bands in air-equilibrated CH₂Cl₂ solution, sensitized singlet oxygen luminescence at 1270 nm is recorded [18, 49, 64, 68]. Indeed, this can provide a good clue for photoinduced energy transfer to the molecular oxygen dissolved in the solvent. However, it has been shown that the intimate nature of excited state quenching by dioxygen is often quite difficult to elucidate [71]. For instance, the occurrence of singlet oxygen luminescence at 1270 nm is necessary (but not sufficient) to demonstrate that energy transfer occurs. In fact, upon encounter of an excited molecule (M) with dioxygen (O₂), electron transfer can be followed by a back electron transfer reaction, yielding singlet oxygen [72]:

Moreover, specific donor–acceptor interactions (e.g., exciplex formation), often related to the oxidation potential of the quencher, can play an important role [71b,c]. Therefore, the actual mechanism for the quenching of the MLCT lowest excited state in $[\text{Cu}(\text{phen})_2]^+$ -type complexes in CH_2Cl_2 solution has not been elucidated, also because the reduction potential of O_2 in dichloromethane solution is not known. However, since such potential has been reported in several organic solvents (e.g., DMF, pyridine, CH_3CN) to be -0.85 V , we can tentatively attribute a potential around 1 V in the less-polar CH_2Cl_2 . Hence, taking the (average) MLCT excited state energy as 1.7 eV and the average oxidation potential for $\text{Cu}^+/\text{Cu}^{2+}$ as 0.6 V , one can argue that electron transfer cannot be excluded. The situation can be schematized as follows:

The Stern–Volmer quenching rate constants were determined for all our knots and catenates [18, 49, 52b, 64, 68], and are in the range $1.1\text{--}2.5 \times 10^6\text{ s}^{-1}\text{ M}^{-1}$. These values, especially when compared to those of mononuclear complexes such as $[\text{Cu}(\text{dmp})_2]^+$ ($\text{dmp} = 2,9\text{-di-}p\text{-methyl-1,10-phenanthroline}$), show a clear trend where the rate constants decrease upon increasing the rigidity of the systems and the protection of the Cu^{I} ion, thus reflecting the increasing steric hindrance toward orbital overlap between the $[\text{Cu}(\text{phen})_2]^+$ -type chromophoric unit and O_2 . Such steric constraints are also evidenced by quenching experiments with acetone [64], although in this case neither energy nor electron transfer are responsible for the observed quenching. This is in fact simply due to the formation of pentacoordinated exciplexes which deactivate via nonradiative paths (see above); however, the rates of such process are also strongly dependent on steric hindrance, and somehow parallel the trend observed for quenching rates by O_2 .

8.4 Porphyrinic Rotaxanes: Control of the Photoinduced Electron Transfer Rate between PZn and PAu^+ by the Assembler Metal

8.4.1 Introduction

The publication in 1984 of the resolution of the X-ray crystal structure of the reaction center (RC) of the photosynthetic bacterium *Rhodospseudomonas viridis* [73] inspired many research groups, and thus initiated the design and synthesis of multifarious multicomponent systems expected both to display structural analogy with the RC and to fulfill some of its photochemical and electron transfer functions [74].

Figure 22. (a) A fragment of the photosynthetic reaction center with the three components: Special Pair (SP), “Accessory” Bacteriochlorophyll (BCh), and Bacteriopheophytin (BPh). Photoinduced electron transfer from SP to BPh takes place at a *global* rate of $(3 \text{ ps})^{-1}$. (b) Principle of the modular mimetic approach. D and A are the donor and acceptor porphyrins, respectively. M is an electron transfer mediator whose introduction between D and A can be realized via coordination of a metal center (solid circle) which will also bind the chelating part of the bisporphyrin spacer.

Mimicking the electron transfer processes occurring within the Special Pair (SP)/Accessory Bacteriochlorophyll (BCh)/Bacteriopheophytin (BPh) trichromophoric fragment, where SP is the excited state electron donor, and BPh the terminal electron acceptor of this triad (Figure 22a) seemed particularly attractive. An oblique bisporphyrin looked appealing since these porphyrin-like nuclei are mostly organized in an oblique fashion to one another. The required electronic properties can be controlled by the nature of the metal centers of each porphyrin. Surprisingly, the number of (M^I , M^2) metal couples fulfilling these requirements is quite limited. Zinc(II) and gold(III) were selected as metals for the donor component and the acceptor subunit respectively, because both metal centers are electroinactive once complexed by a porphyrin, and all the expected properties are in agreement with the objective. Noteworthy, the (Zn^{II} , Au^{III}) strategy is reminiscent of the photosynthetic RC. In nature, energy transfer has been avoided by decreasing the energy level of the donor, using a bacteriochlorophyll dimer (the SP), whereas in the present approach the same effect is obtained by raising the excited state level of the electron acceptor (Au^{III} porphyrin). Finally, a *modular approach* was particularly attractive in order to introduce chemical groups, supposed to control the electron transfer rate between D and A. The use of a chelate as spacer between both porphyrin components allowed for the insertion of an aromatic group via coordination to a transition metal whose function was both to serve as structural element (gathering center) and to tune the electronic properties of the third component interspersed between D and A. The principle is indicated in Figure 22b. The most thoroughly studied bisporphyrin **19** and Cu^I -complexed [2]rotaxane **Cu.20⁺** of Figure 23 were selected among the systems that were designed and synthesized for this purpose [75, 76].

Figure 23. Chemical structures of Zn/Au bisporphyrin **19**, Cu^I-complexed [2]rotaxane **Cu.20⁺**, and the model compounds **21–24**.

8.4.2 Properties of the Reference Compounds

Photophysical and electrochemical data recorded for the reference compounds **21–24** of Figure 23 are collected in Table 14. Additional data corresponding to bisporphyrins **19** and **Cu.20⁺** are given in Table 15, and were used to calculate the exothermicities of the electron transfer reactions occurring in these compounds. The Zn porphyrins **21** and **22** fluoresce in DMF at room temperature but, as expected, Au porphyrin **23** is non fluorescent. Phosphorescence from **22** and **23** was observed in methanol glasses at 77 K.

Transient differential absorption spectra were recorded for **22** and **23** after excitation with a 30-ps laser pulse at 532 nm. For **22**, the transient spectrum is assigned to the first excited singlet state. This species decays on the nanosecond time scale to produce a long-lived triplet excited state. The spectrum observed for **23** decays via first-order kinetics with a lifetime of 1.4 ns to reform the ground state, which is assigned to the first excited triplet state.

[Cu(dpp)₂]⁺ (**24**) has a long-lived MLCT excited state, which is luminescent at room temperature. Stabilization of Cu^I by the dpp ligand is evident from the unusually high oxidation potential of [Cu(dpp)₂]⁺.

8.4.3 Photochemistry of the Zinc/Gold Bisporphyrin

Upon selective excitation at 598 nm of the Zn^{II} porphyrin component of **19**, a weak fluorescence, with a quantum yield of 0.0012 and a lifetime of 55 ps, is observed, which corresponds to ca. 97 % fluorescence quenching. Excitation of **19** with a 30-ps

laser pulse at 598 nm, forms the excited singlet state of the Zn porphyrin (Figure 24a, trace 0 ps) as identified by comparison with the spectrum obtained for **22**. This excited state decays rapidly to form a transient exhibiting absorptions at 440 nm and between 640 and 750 nm (trace 100 ps) and which decays itself with a lifetime of 600 ps (Figure 24b). This transient can be assigned to a charge-transfer (CT) state in which the Zn porphyrin is a π -radical cation and the Au^{III} porphyrin a neutral radical:

Decay of the CT state regenerates cleanly the ground-state bisporphyrin:

Immediately after excitation of **19** with a 30-ps laser pulse at 532 nm, where the Au porphyrin subunit absorbs ca. 85 % of incident photons, the Au porphyrin excited triplet state can be identified (Figure 24c) by comparison with the spectrum obtained for **23**. This species (trace 0 ps) decays with a lifetime of 120 ps to form a mixture of two products. The shorter-lived product (trace 0.8 ns), which accounts for 77 % of the decay of the Au porphyrin excited triplet state, corresponds to the CT state, as described for 598 nm excitation:

It decays with a lifetime of 570 ps due to reverse electron transfer (Figure 24d). The longer-lived product (trace 1.5 ns) is the triplet excited state of the Zn porphyrin subunit, obtained in ca. 15 % yield by energy transfer from the Au porphyrin triplet. It decays with a lifetime of 1.3 ns, possibly by intramolecular electron transfer to the appended Au porphyrin.

In summary, excitation of either porphyrin subunit in **19** results in electron transfer from Zn to Au porphyrins to form the CT state. For the Zn porphyrin, both singlet and triplet excited states function as electron donors, whereas for the Au porphyrin, intersystem crossing to the triplet manifold is quantitative and the triplet acts as an electron acceptor. The rate constants and reaction exoergonicities for the ET steps described above are compiled in Table 16.

8.4.4 Photochemistry of the Copper(I)-complexed Zinc/Gold Bisporphyrin-Stoppered [2]Rotaxane

The sequence of events following excitation of either porphyrin of the **Cu.20**⁺ [2]rotaxane is depicted in Figure 25.

Excitation into the Zn^{II} porphyrin component

Upon selective excitation of **Cu.20**⁺ at 586 nm, extremely weak fluorescence could be observed, corresponding to >99 % quenching. Immediately after excitation with

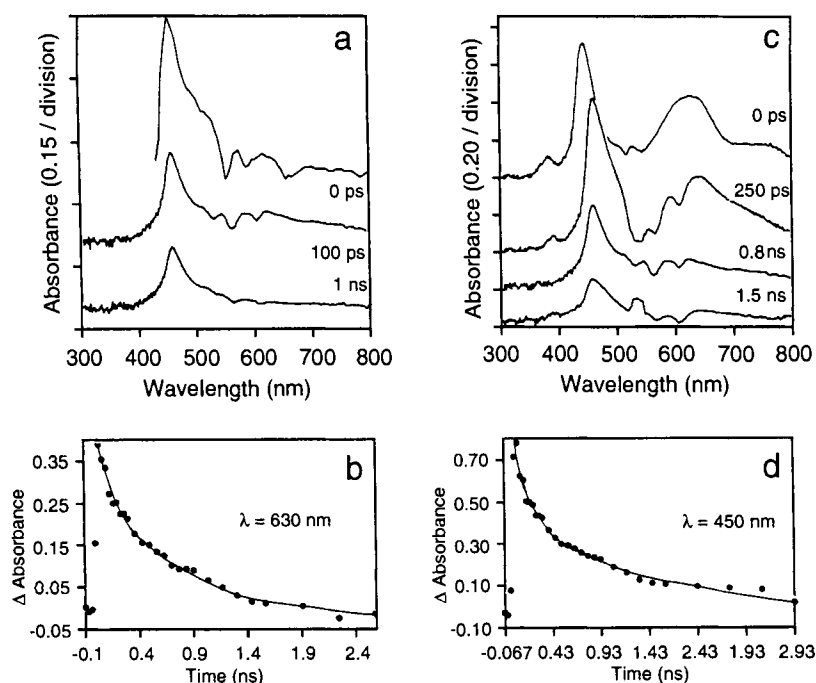

Figure 24. (a) Transient absorption spectra recorded after excitation of **19** in DMF with a 30-ps laser pulse at 598 nm; delay times are given on the traces. (b) Typical kinetic trace observed for the conditions as in (a). (c) Transient absorption spectra recorded after excitation of **19** in DMF with a 30-ps laser pulse at 532 nm. (d) Typical kinetic trace observed for the conditions as in (c).

a 0.5-ps laser pulse at 586 nm, the characteristic differential absorption spectral features of the CT state were observed (Figure 26a and b):

The Zn porphyrin excited singlet state could not be resolved, and formation of the CT state followed the laser pulse profile (Figure 26c). Therefore, the lifetime of the Zn porphyrin excited singlet state was <1 ps.

Absorbance attributed to the CT state decayed with a lifetime of 20 ps (Figure 26d) to leave a residual species having the characteristic differential absorption spectrum of the Au porphyrin neutral radical (Figure 26a and b). Deactivation of the CT state may involve direct reverse electron transfer between porphyrinic species:

or ET from the central copper(I) complex to the Zn porphyrin π -radical cation:

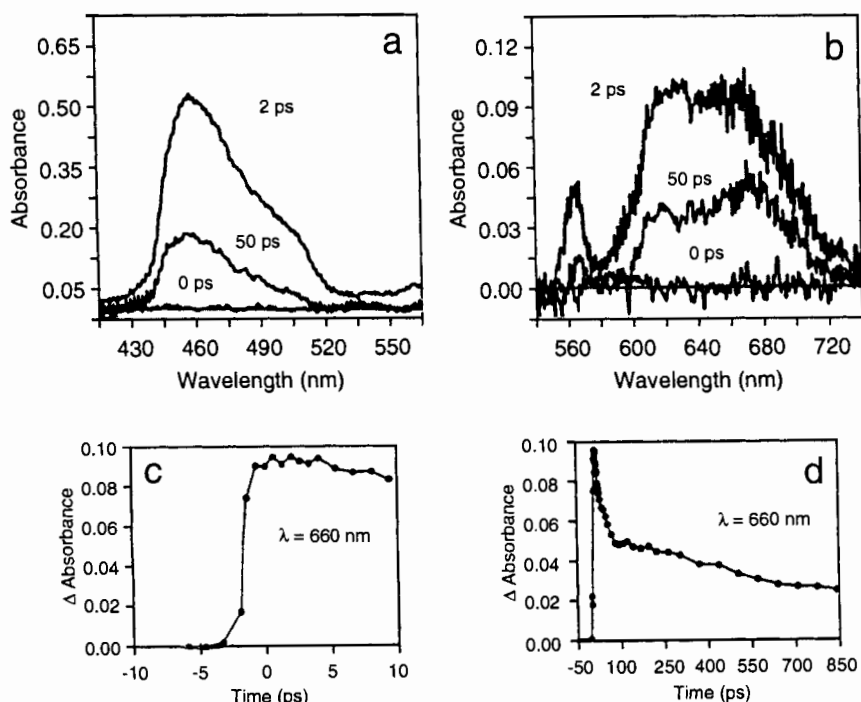

Figure 26. (a, b) Transient differential absorption spectra recorded after excitation of **Cu.20⁺** in DMF with a 0.5-ps laser pulse at 586 nm; delay times are given on the traces. (c) Growth of the transient absorbance at 660 nm attributed to the charge-transfer state. (d) Decay profile recorded for the above experiment at 660 nm. Note its clear biphasic nature.

On the basis of differential molar absorption coefficients, the latter process appears to be quantitative. Indeed, using the rate constant for direct reverse electron transfer (Eq. 18) derived following excitation into the Au porphyrin subunit ($k_{18} = 2.0 \times 10^9 \text{ s}^{-1}$), oxidation of the central **Cu^I** complex ($k_{19} = 4.8 \times 10^{10} \text{ s}^{-1}$) should account for ca. 95 % of the total decay of the intermediate CT state. The residual Au porphyrin neutral radical decayed on a much longer time scale (Figure 26d) due to electron donation to the **Cu²⁺** complex:

The most reliable estimate of the rate constant for Eq. 20 ($k_{20} = 4.0 \times 10^8 \text{ s}^{-1}$) was obtained following excitation of **Cu.20⁺** with a 30-ps laser pulse at 559 nm.

Excitation into the **Au^{III}** porphyrin component

Excitation of **Cu.20⁺** with a 30-ps laser pulse at 532 nm, where the Au porphyrin subunit absorbs about 80 % of the total incident photons, resulted in formation of the Au porphyrin triplet excited state. This species decayed within the laser pulse to

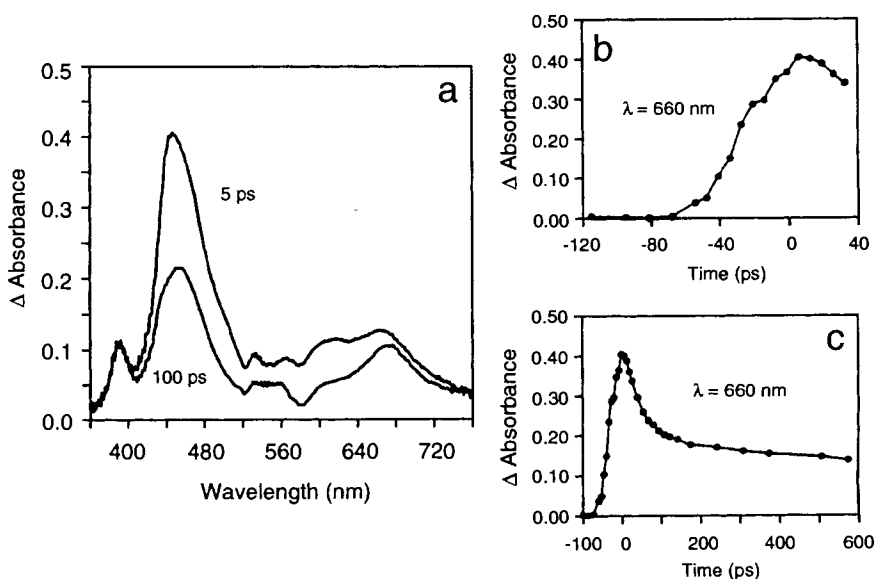

Figure 27. (a) Transient differential absorption spectra recorded after excitation of **Cu.20⁺** in DMF with a 30-ps laser pulse at 532 nm; delay times are given on the traces. (b) Growth of the transient absorption at 660 nm attributed to the charge-transfer state. (c) Decay profile recorded for the above experiment at 660 nm.

form the CT state (Figure 27b), as detected by its transient differential absorption spectrum (Figure 27a).

The lifetime of the Au porphyrin excited triplet state was derived as 17 ps.

The CT state was found to decay rapidly (Figure 27c), with a lifetime of 50 ps, leaving a residual absorbance which was identified as the Au^{III} porphyrin neutral radical by virtue of its differential absorption spectrum. This latter species decayed relatively slowly, with a lifetime of 2.5 ns, to re-form the ground state of **Cu.20⁺**. As above, the rapid deactivation of the CT state is ascribed to a combination of direct reverse electron transfer (Eq. 18) and oxidation of the central copper(I) complex by the Zn porphyrin π -radical cation (Eq. 19). The yield of the $\text{Au}(\text{III})$ porphyrin neutral radical which escaped direct electron transfer was estimated from the transient absorption spectral changes to be 90 %. Thus, direct reverse electron transfer ($k_{18} = 2.0 \times 10^9 \text{ s}^{-1}$) accounts for only 10 %, and electron abstraction from the central copper(I) complex ($k_{19} = 1.8 \times 10^{10} \text{ s}^{-1}$) is the dominant decay route. The residual Au porphyrin neutral radical decays over several nanoseconds due to electron donation to the copper(II) complex (Eq. 20).

8.4.5 Comparison of the Electron Transfer Rates for both Systems

The reactions that lead to reoxidation of the Au^{III} porphyrin neutral radical are relatively slow and dissipate large amounts of energy, although there is no reason to suppose that they fall within the Marcus inverted region. The copper(I) complex exerts no significant effect on the rate of direct reverse electron transfer (compare k_{18} and k_{15}). That $k_{18} > k_{20}$ is in accord with the relative reaction exoergonicities, and the fact that reduction of the copper(II) complex, which is initially formed as a coordinatively unsaturated species, may involve a high reorganization energy.

It is noteworthy that the rate of reduction of the Zn porphyrin π -radical cation by the copper(I) complex is much faster than direct charge recombination between the porphyrin radicals, although the reaction exoergonicity for Eq. 19 is very much less than that for Eq. 18. The faster rate for Eq. 19 may arise because of the closer proximity of the reactants and/or because electron transfer occurs via a different route. In addition, k_{19} shows some dependence on the porphyrin donor. This effect could be due to a different spin multiplicity of the precursor excited state.

The most striking difference in reactivity between the bis-porphyrin **19** and the rotaxane **Cu.20**⁺ concerns the relative rates of *photoinduced* electron transfer. Regardless of which porphyrinic subunit is excited, the rate of photoinduced electron transfer is very much faster in **Cu.20**⁺ (k_{17}) than in **1** (k_{14}). This cannot be explained alone by higher reaction exoergonicities (see Table 16), which arise because the Zn porphyrin subunit in **Cu.20**⁺ has a higher excited singlet state energy [78]. Since the mutual arrangement of the two porphyrin nuclei of **Cu.20**⁺ is not expected to differ significantly from that in the bisporphyrin **19**, it is tempting to invoke a super-exchange effect to account for the large difference between k_{14} and k_{17} . There are at least two distinct ways for this to happen. Firstly, the copper(I) complex might modulate the energy of the relevant HOMO or LUMO orbitals on the bridging unit; this would be significant if electron transfer occurs through the spacer moiety. Secondly, the “accessory” 1,10-phenanthroline residue contained in the 30-membered macrocyclic ring of the rotaxane **Cu.20**⁺ could also mediate electron transfer since it is interspersed between the two porphyrin rings. This latter mechanism would be significant if electron transfer proceeded through space.

It is remarkable that the relative rates of electron transfer observed for both compounds can be qualitatively explained in terms of a simple orbital energy diagram of the type displayed in Figure 28. Here, the energies of the donating and accepting orbitals on the Zn^{II} and Au^{III} porphyrins are compared to the energies of the LUMO and HOMO on the 2,9-diphenyl-1,10-phenanthroline spacer moiety. For reaction to proceed via electron transfer through the LUMO of the spacer moiety, it is important to minimize the energy gap (B_-) between the donating orbital and the LUMO. Conversely, for reaction to proceed via hole transfer through the HOMO of the spacer moiety, it is important to minimize the energy gap (B_+) between the accepting orbital and the HOMO. The energy gaps have been calculated for each of the electron transfer reactions and are listed in Table 17.

The calculated energy gaps indicate that reaction from the first excited singlet state of the Zn porphyrin should proceed by way of electron transfer through the LUMO of the spacer. Accordingly, the rate of electron transfer is the highest for

Figure 28. Orbital energy level diagram for (a) photoinduced ET from the excited singlet state of the Zn porphyrin, (b) photoinduced ET from the excited triplet state of the Au porphyrin, and (c) direct reverse ET. Values for the energy gaps (B_- and B_+) are listed in Table 17.

Table 17. Energy gaps for the various electron transfer steps between porphyrinic species within **19** and **Cu.20**⁺^a

	$k/10^8$ (s ⁻¹)	ΔG° (eV)	B_-^b (eV)	B_+^b (eV)
Electron transfer from *ZnP				
19	178	-0.75	0.56	2.44
Cu.20 ⁺	>10 000	-1.01	0.15	2.39

19	17	-1.31	1.51	1.13
Cu.20 ⁺	20	-1.17	1.16	1.22

^aFrom Ref. [76b]; it is assumed that reaction proceeds by way of the spacer moiety.

^bCalculated using the appropriate redox potentials and the excited state energy values (Tables 14 and 15). The energy of the bridge LUMO was calculated using the reduction potential of free dpp (-2.00 V) in the case of **19**, and the reduction potential of [Cu(dpp)₂]⁺ (-1.65 V) for **Cu.20**⁺. The energy of the bridge HOMO was calculated using the oxidation potential of free dpp (+1.95 V) in the case of **19** and the ligand-centered oxidation potential of [Cu(dpp)₂]⁺ (+1.90 V) for **Cu.20**⁺.

Cu.20⁺, which has the lowest B_- . On the other hand, the Au^{III} porphyrin triplet is more likely to react via hole transfer through the HOMO of the spacer. However, there is a small decrease of the energy gap (B_+) upon coordination of a copper(I) cation to the bridging dpp moiety, which is nevertheless accompanied by an increase in the rate of electron transfer. This rate acceleration is modest by compari-

son with the former case, and could be explained, at least in part, by differing ΔG° values for electron transfer. The rate of direct reverse electron transfer (k_{15} or k_{18}) remains insensitive to the molecular architecture, within experimental limits. The slow rates observed appear consistent with the large energy gaps, and there seems to be no preferred pathway for this process. Overall, it appears that the rates of electron transfer between porphyrinic species are well explained in terms of the simple superexchange model involving electron or hole transfer through orbitals of the spacer moiety.

8.4.6 Conclusion

The studies described in this section were started shortly after the X-ray crystal structure of the RC of *Rh. viridis* was disclosed [73]. During these years, the role of the so-called accessory bacteriochlorophyll BCh was under debate [79]. In particular, the possibility was considered that it could play the role of a superexchange relay between SP and BPh (see Figure 22). In this respect, the copper(I)-complexed [2]rotaxane **Cu.20**⁺ represented a functional artificial model of the SP/BPh/BCh triad, the central Cu^I complex fragment between the Zn porphyrin donor and the Au porphyrin acceptor mimicking the function of BCh between SP and BCh. However, the kinetic scheme shown in Figure 22a has been revised, being now quite firmly established that (at least at room temperature) BCh is directly involved in the electron transfer reaction: the transfer from the electronically excited special pair SP* to BCh takes about 3 ps, and the next transfer step to the BPh, 0.65 ps [80]. In the earlier experiments, detection of the intermediate state SP⁺BCh[−] was prevented by its relatively slow population and fast decay.

Undoubtedly, if not a 273 K model of the SP/BCh/BPh triad, the copper(I)-complexed [2]rotaxane **Cu.20**⁺ remains a most elegant example of control by “external” complexation of the electron transfer rate between covalently linked donor and acceptor porphyrins.

8.5 Catenanes in Motion: Electrochemically and Photochemically Driven Machine-Like Molecules

8.5.1 Introduction

The early synthesis [1a, 81] of topological complex systems like catenanes, where the components are mechanically linked, allowed the chemical community to face unusual systems where large molecular motions could occur without implying any covalent bond breaking. This was intellectually very stimulating, but of mere academic interest until the development of synthetic methods based on various template effects [3b, 82, 83] which, affording a more accessible synthesis and allowing the inclusion of functional fragments in the structure of interlocked rings, made

these structures available in a large variety and good yields. The ambition to control by external stimuli the large amplitude motions allowed by this topology, with the possibility to store the delivered information, was the obvious consequence. Some of these systems, mostly those of amide-type [83] based on weak interactions such as hydrogen bonds, are characterized by the existence of several accessible minima in the coordinate relative to rotation of one ring around the other. Therefore, at room temperature a wide distribution of conformations can exist, which makes them ideal candidates for the study of dynamic processes in these compounds [84]. Though the relative distribution of the different “isomers” in these type of catenane can be controlled to some extent by a judicious use of solvent [85], or by geometric constraints due to bulky substituents [83, 86], more rigid systems can offer several advantages to the approach of externally driven ring motion. The relative ring position of a catenane which has to experience an external stimuli inducing rotation should, in fact, be constant during the time of action of the external stimuli and, to be effective in storing the information, should produce a different and stable geometry. In this respect catenanes based on stronger interactions as is the case of coordination bonds [28, 82, 87] and of electron donor–acceptor interactions [88] have to be preferred. As stressed above, the external stimuli has to produce a different “isomer” than the initial state, so some type of asymmetry is mandatory in a catenane which has to accomplish this task (Figure 29).

A critical parameter being reversibility, it should be possible to revert any externally induced motion to produce the starting structure so that the cycle can be repeated at will. A less critical, but not negligible, parameter is the time needed by the external action to be effective. Fast response times can be of great importance for some of the possible applications.

As far as the external action is concerned, several external stimuli can be conveniently used to achieve rotation of one ring into the other; some success has been achieved by chemical means like addition of protons [60, 89, 90], demetalation of catenates [90, 91] or change of solvent [85], but by far the most convenient system for its ease of control is a redox action which can be either chemically, electrochemically, or photochemically induced. The latter method, based on light-induced electron transfer processes, could take advantage of the development of laser technology and grant a complete control both in the space and in the time domain.

To date, few examples of electrochemically switchable [2]catenanes have been reported. One of those recently reported by Balzani and colleagues [92] incorporates

Figure 29. Schematic representation of a ring motion producing a different isomer in a [2]catenane.

Figure 30. An example of externally induced ring rotation in a [2]catenane [92]. The motion could be triggered either electrochemically or chemically.

a tetrathiafulvalene (TTF) as redox active unit. In the solid state, the TTF unit resides in the inside of the cyclobis(paraquat-*p*-phenylene) tetracationic cyclophane by virtue of charge–transfer interactions; the same arrangement is maintained in acetonitrile solution, but upon oxidation of the TTF unit the 1,5-dioxynaphthalene moiety of the macrocycle moves to the inside of the tetracationic cyclophane to minimize charge repulsion.

The process (Figure 30)—which can be switched also chemically by using *o*-chloranil or $\text{Fe}(\text{ClO}_4)_3$ as oxidants, and $\text{Na}_2\text{S}_2\text{O}_5$ or ascorbic acid as reductants to complete the cycle—was detected both spectroscopically and by cyclic voltammetry, and is reversible and highly exclusive. A previously reported example by the same groups, of an electrochemically triggered ring rotation in a [2]catenane based on *trans*-bis(pyridinium)ethylene unit, was less exclusive than the present one, and was found to allow for some distribution of conformations [93]. For a detailed discussion of chemically, photochemically, and electrochemically induced motions in this kind of catenanes, see Volume III, Part 2, Chapter 7.

The other examples of electrochemically driven ring motions in [2]catenanes are from the class of metal complexed catenanes (i.e., catenates) that have been synthesized and studied in our groups. These compounds, the synthesis of which relies on the ability of copper(I) to gather the bidentate phenanthroline ligand around its tetrahedral coordination sphere, are produced in remarkable yield [9, 28, 57f]. The principle of operation is essentially based on the different stereoelectronic requirements of copper(I) and copper(II). Whereas a coordination number of 4, with a tetrahedral or distorted tetrahedral arrangement is preferred by copper(I),

Cu.25⁺

Figure 31. The nonsymmetrical copper [2]catenate **Cu.25⁺**.

copper(II) requires higher coordination numbers generally 5 or, even better, 6. The penta-coordination corresponds to either a square pyramidal or to a trigonal bipyramidal arrangement, the hexa-coordination to a distorted octahedral arrangement. If the interlocking rings can provide a tridentate ligand, in addition to the bidentate phenanthroline, the different requirements of the copper in the two oxidation states will provide the driving force for inducing the motion. Other transition metal complexes have been shown to undergo rearrangements following changes in the metal oxidation states [94].

8.5.2 A Nonsymmetrical Copper [2]Catenate

The first successful structure of this type is the catenate shown in Figure 31, where a gliding motion of one ring over the other could be triggered electrochemically [95, 96] and photochemically [96].

The nonsymmetrical catenate **Cu.25⁺** consists of the two different rings **26** and **27** reported in Figure 32: one includes the classical bidentate dpp and a polyoxoethylene chain; the other incorporates a dpp moiety and the terdentate ligand 2,2':6',2''-terpyridine (tpy), linked by three methylene groups. Both macrocycles have a 33 atom-long internal rim to minimize the hindrance toward rotation of one ring over the other.

Figure 32. Macrocycles constituting the rings of the nonsymmetrical and symmetrical copper [2]catenate.

Figure 33. Principle of operation for inducing ring rotation in a nonsymmetrical [2]catenate. Horizontal arrows represent redox processes, vertical arrows represent rearrangements. Cu^{II} is a solid circle, whereas Cu^{I} is an open circle. The stable four-coordinate monovalent complex $\text{Cu}^{\text{I}}_{(4)}$ (top left) is oxidized to the intermediate tetrahedral divalent species $\text{Cu}^{\text{II}}_{(4)}$ (top right) which rearranges to the stable five-coordinate $\text{Cu}^{\text{II}}_{(5)}$ complex, bottom right. Upon reduction, the five-coordinated monovalent $\text{Cu}^{\text{I}}_{(5)}$ is formed (bottom left) which finally undergoes conformational changes to restore the starting $\text{Cu}^{\text{I}}_{(4)}$ (top left).

Electrochemical or chemical triggering

The principle of operation is shown schematically in Figure 33; horizontal arrows represent redox action, and vertical arrows represent rearrangements.

Following oxidation of the stable monovalent four-coordination state $\text{Cu}^{\text{I}}_{(4)}$, an intermediate tetrahedral divalent species $\text{Cu}^{\text{II}}_{(4)}$ is formed. The latter compound undergoes a complete rearrangement process which requires gliding of the macrocycle, to afford the stable five-coordinate bivalent complex $\text{Cu}^{\text{II}}_{(5)}$. Its reduction yields the transient five-coordinate monovalent copper $\text{Cu}^{\text{I}}_{(5)}$, which regenerates the starting species $\text{Cu}^{\text{I}}_{(4)}$ upon conformational change. The actual system and the changes corresponding to the redox steps discussed above are reported in Figure 34.

The species $\text{Cu}^{\text{I}}_{(4)}$ and $\text{Cu}^{\text{II}}_{(5)}$ are stable species which can be independently synthesized and characterized from a spectroscopic and electrochemical viewpoint. In acetonitrile solutions the monovalent species $\text{Cu}^{\text{I}}_{(4)}$ is brown-red in color, with a metal to ligand charge transfer (MLCT) absorption band around 470 nm ($\epsilon = 2500 \text{ M}^{-1} \text{ cm}^{-1}$) and a redox potential of the couple $\text{Cu}^{\text{II}}/\text{I}$ of +0.63 V versus SCE. The penta-coordinate $\text{Cu}^{\text{II}}_{(5)}$ ion in acetonitrile is characterized by an absorption band peaking around 640 nm ($\epsilon = 125 \text{ M}^{-1} \text{ cm}^{-1}$), which corresponds to a d-d transition, and a redox potential of -0.07 V versus SCE, indicating a strong stabilization of the bivalent copper in the penta-coordinate geometry.

Figure 34. Square scheme illustrating the response of the catenane **Cu.25⁺** to an electrochemical signal. Oxidation and reduction generates metastable complexes which rearranges to adopt the best coordination mode for the new oxidation state of the copper center. Cu^{II} is a black circle and Cu^{I} is an open circle. (For the notation used here, see Figure 33.)

Upon chemical (by Br_2 or NOBF_4) or electrochemical oxidation on a platinum electrode (+0.8 V versus SCE), the red-brown colored solution of the $\text{Cu}^{\text{I}}_{(4)}$ catenane turns dark green. This corresponds to the progressive disappearance of the MLCT band with maximum at 470 nm typical of the $\text{Cu}^{\text{I}}_{(4)}$ and to the appearance of a new band with a maximum at 670 nm ($\epsilon = 800 \text{ M}^{-1} \text{ cm}^{-1}$). The position and intensity of this band is in agreement with tetra-coordinated dpp complexes of copper(II) [7, 28]. A cyclic voltammogram of the green solution shows a reversible wave centered at +0.63 eV, supporting the assignment. A thermal, slow reaction follows and changes the solution to a pale yellow-green color; this can be detected spectroscopically as a general decrease and shift to 640 nm of the original 670 nm band. Cyclic voltammograms on this solution indicate the appearance of a signal at -0.07 eV, while the +0.63 V signal decreases. On completion of the reaction the species in solution can be identified, by its spectral and electrochemical properties, as the penta-coordinate copper(II). This has occurred by rotation of the macrocycle with the two different units (bidentate and terdentate). A subsequent reduction by chemical (using ascorbic acid) or electrochemical methods regenerates the original red-brown color and a unique signal at +0.63 V, typical of the starting Cu^{I} catenane. Thus, a further gliding motion of the ring—opposite to the one triggered by oxidation—has occurred. More evidence of this rotation mechanism was obtained by electron paramagnetic resonance (EPR) spectroscopy, which also demonstrated for $\text{Cu}^{\text{II}}_{(4)}$ a distorted tetrahedral and for $\text{Cu}^{\text{II}}_{(5)}$ a square pyramidal coordination geometry [97]. The rates of the two changeover steps from tetra- to penta-coordination of the Cu^{II} and vice versa for Cu^{I} , are noticeably different. The pro-

cess involving rearrangement of the Cu^{I} coordination sphere is relatively fast (a few seconds at room temperature regardless of the solvent), whereas the Cu^{II} complex rearrangement is slow, allowing for the isolation of the intermediate $\text{Cu}^{\text{II}}_{(5)}$. The latter process depends strongly on the experimental conditions: a few minutes in anhydrous acetonitrile, but hours or even days in noncoordinating solvents or in the absence of coordinating counterions. Indeed, coordinating solvents and counterions can assist the rearrangement by stabilizing some intermediate state [96–98].

Photochemical triggering

One of the peculiarities of this system is that the motion can also be triggered photochemically [96]. The principle of operation is based on the fact that the MLCT excited state of the Cu^{I} complexes of polypyridine type can play the role of an electron transfer reagent. Its lifetime in aerated acetonitrile is sufficiently long (60 ns) to be able to intercept a reactant if this is in a sufficiently high concentration. The redox potential of the couple $\text{Cu}^{\text{II}}_{(4)}/\text{*Cu}^{\text{I}}_{(4)}$ (evaluated to be ca. -1 V versus SCE from the spectroscopic and electrochemical data) indicates that even a mild oxidant that is ineffective on the ground state $\text{Cu}^{\text{I}}_{(4)}$ can oxidize the photoexcited $\text{*Cu}^{\text{I}}_{(4)}$. The oxidant of choice, in addition to its ability to efficiently oxidize the excited state of the copper(I) during its short lifetime, must accomplish several requirements related to its spectroscopic features (i.e., no absorption in the visible region), and it must be possible to remove the reduced products from the solution mixture. This is necessary to prevent any back electron transfer in the reaction mixture. After a thorough search, the oxidant chosen—which could fulfill all the requirements—was *p*-nitrobenzylbromide. Illumination of the reaction mixture by visible light produced the spectral changes shown in Figure 35, indicating the disappearance of the MLCT band of $\text{Cu}^{\text{I}}_{(4)}$ complex and the concomitant formation of the $\text{Cu}^{\text{II}}_{(4)}$ band

Figure 35. Spectral changes induced by excitation at 464 nm of an acetonitrile solution containing 1.0×10^{-4} M Cu.25^+ and 5×10^{-2} M *p*-nitrobenzylbromide. The initial spectrum (i) and final spectrum after 20 nm irradiation (f) are evidenced. The isosbestic point is at 625 nm.

Figure 36. Absorption spectra of an acetonitrile solution of **Cu.25⁺**: (a) before light excitation; (b) at the end of the photoreaction with *p*-nitrobenzylbromide, (20 min irradiation); (c) 24 h later in the dark; (d) 30 min after addition of ascorbic acid.

with a maximum around 670 nm. On completion of the reaction, the spectrum slowly evolved to a new one characterized by a lower absorbance and a new band with low intensity around 640 nm. The latter spectrum is consistent with a complete conversion of the copper(II) complex to the penta-coordinate $\text{Cu}^{\text{II}}_{(5)}$. At this stage, in order to complete the cycle, ascorbic acid was used as reductant, and within 30 min a complete recovery of the initial $\text{Cu}^{\text{I}}_{(4)}$ spectral features occurred.

The spectra of the various stages of the reaction are shown in Figure 36. The complete agreement of the photochemical results with those induced electrochemically clearly shows that the ring motion can also be induced by light. The reduction step to complete the cycle was induced chemically, but in principle this could also be photochemically driven by using the excited state $^*\text{Cu}^{\text{II}}_{(5)}$ as an electron transfer reagent. The difficulty in this case resides in the short lifetime of the $^*\text{Cu}^{\text{II}}_{(5)}$ state, which would require a too high concentration of reductant to be able to interact with the short-lived excited state in a diffusional process. Furthermore, the presence in solution of the unreacted oxidant *p*-nitrobenzylbromide, which had to be used in high concentration to intercept the excited state, would be a complicating feature.

The same principle illustrated above was also used to trigger by electrochemical and photochemical techniques the motion of a dpp-containing macrocycle in a [2]rotaxane [99], see 8.6.

8.5.3 A Symmetrical Copper [2]Catenate

The scheme reported in Figure 33, which is based on two different states, can be further implemented if one could rely on three different geometries. An increase in

Figure 37. The symmetrical copper [2]catenate **Cu.28⁺**.

Cu.28⁺

the number of possible isomers would greatly enhance the information density which can be stored in this device. The quantity of information which could be stored by an array of n systems with three different states is 3^n , in contrast to the 2^n quantity which would be stored by an array containing the same number of systems but with only two states. This implementation was achieved by providing the conditions for the formation of a six-coordinated copper complex in the [2]catenate. The actual system **Cu.28⁺** is shown in Figure 37, and is based on the use of the two identical macrocycles **27** of Figure 32, both containing the bidentate dpp and the terdentate tpy ligands [100]. This would allow for the formation of a hexa-coordinated species, which incidentally is the coordination number preferred by the bivalent copper, via two terdentate ligands. The schematic diagram of the principle of operation of the system is shown in Figure 38 (the nature of the arrows is defined in Figure 33).

In this case the system can adopt three distinct geometries, which can interconvert and are triggered by an electrochemical action [100]. The initial tetra-coordinated Cu^I₍₄₎ complex can be oxidized to a tetra-coordinated copper(II), Cu^{II}₍₄₎, which then rearranges by gliding of one ring to the penta-coordinated Cu^{II}₍₅₎ as already seen in the previous case. However, the action can continue in this case and the more stable hexa-coordinate Cu^{II}₍₆₎ can be formed by gliding of the other macrocycle. The process can be reversed by reduction of the stable Cu^{II}₍₆₎ (bottom right); at first the Cu^I₍₆₎ is obtained which rearranges to Cu^I₍₅₎ and by a further gliding of one ring to the starting Cu^I₍₄₎. Some of the different conformations of **Cu.28⁺** could be independently synthesized and their spectroscopic and electrochemical properties probed. The visible spectrum of Cu^I₍₄₎ in acetonitrile has an absorption MLCT band at 439 nm ($\epsilon = 2750 \text{ M}^{-1} \text{ cm}^{-1}$), and its cyclic voltammetry shows a reversible oxidation process at +0.63 V versus SCE. Demetalation of this species and re-metalation by Cu^{II} afforded the Cu^{II}₍₆₎ species, with two terpyridine coordinated, as confirmed by its spectroscopic and electrochemical properties in agreement with reference Cu^{II}–tpy complexes [100]. In acetonitrile, this species is characterized by a very weak visible band with a maximum at 687 nm ($\epsilon = 100 \text{ M}^{-1} \text{ cm}^{-1}$) and by an irreversible reduction at –0.43 V versus SCE.

Figure 38. Principle of operation for inducing ring rotation in a symmetrical [2]catenate. Horizontal arrows represent redox processes, vertical arrows represent rearrangements. Cu^{II} is a black circle, whereas Cu^{I} is an open circle. The stable four-coordinate monovalent complex $\text{Cu}^{\text{I}}_{(4)}$ (top left) is oxidized to the intermediate tetrahedral divalent species $\text{Cu}^{\text{II}}_{(4)}$ (top right), which rearranges to the five-coordinate $\text{Cu}^{\text{II}}_{(5)}$ complex (middle right). Upon rearrangement of the other ring, the stable hexa-coordinate bivalent $\text{Cu}^{\text{II}}_{(6)}$ is formed (bottom right). Reduction of the latter yields the esa-coordinated monovalent $\text{Cu}^{\text{I}}_{(6)}$ (bottom left) which upon consecutive gliding motions converts at first to the five-coordinated monovalent $\text{Cu}^{\text{I}}_{(5)}$ (middle left) and finally to the starting $\text{Cu}^{\text{I}}_{(4)}$ (top left).

In practice this system was put to work by electrochemical action [100]. Oxidation of the starting $\text{Cu}^{\text{I}}_{(4)}$ yielded the $\text{Cu}^{\text{II}}_{(4)}$ species with its typical 670-nm band, as discussed for the previous bistable system. The rearrangements to $\text{Cu}^{\text{II}}_{(5)}$ and to $\text{Cu}^{\text{II}}_{(6)}$ could not be resolved, even if the overall process was rather slow (minutes or hours), and was strongly affected by the presence of coordinating solvents or ions, as previously discussed. The final point of the oxidation reaction, $\text{Cu}^{\text{II}}_{(6)}$, was clearly characterized by spectro- and electrochemical properties. Interestingly, the oxidation step from $\text{Cu}^{\text{I}}_{(4)}$, through the intermediate $\text{Cu}^{\text{II}}_{(5)}$, to $\text{Cu}^{\text{II}}_{(6)}$, could also be triggered chemically by using the oxidant NOBF_4 . The back reaction to close the cycle was electrochemically controlled. Reduction at 1 V of the hexa-coordinated copper(II) yielded quantitatively the $\text{Cu}^{\text{I}}_{(4)}$ starting compound, and the cycle was

$$\text{Cu}^{\text{II}}(4)/\text{Cu}^{\text{I}}(4); E^0 = +0.63\text{V}$$

$$\text{Cu}^{\text{II}}(5)/\text{Cu}^{\text{I}}(5); E^0 = -0.05\text{V}$$

$$\text{Cu}^{\text{II}}(6)/\text{Cu}^{\text{I}}(6); E^0 = -0.41\text{V}$$

Figure 39. Different coordination geometries for **Cu.28**⁺. The redox potential for the Cu²⁺/Cu⁺ couple in the different coordinations is also reported, showing the sequence of preferred stabilities for copper(II) versus copper(I).

completed. The changeover process for the copper(I) complexes was faster than the rearrangement of copper(II) complexes, as was previously observed with the bistable system. The existence of the three different coordination geometries for the monovalent metal was probed by cyclic voltammetry, which shows waves at +0.63 V (typical of tetravalent copper), −0.41 V, and −0.05 V, and these agree well with the six- and five-coordinated complexes. The three different coordination geometries with the pertinent redox potentials are shown in Figure 39.

The scheme shown in Figure 38 was put in operation, as shown by the spectro- and electrochemical characterization of the intermediates involved. Nevertheless, complete control of the cycle—with the possibility of isolating each of the three different topographies corresponding to the different coordination numbers 4, 5, and 6—has not been possible. The penta-coordinate species could not be isolated, i.e., the motion could not be stopped at this stage, neither in the oxidation nor in the reduction step.

The present examples are intended to demonstrate the potential of the copper catenanes as mobile, electro- and photoactive components in the design of molecular devices which may be of use in the development of electron transfer-driven molecular machines.

8.6 Rotaxanes: Gliding of the Ring on its Axle under the Action of an Electrochemical or Photochemical Signal

8.6.1 Introduction

A [2]rotaxane is a molecular system consisting of a ring threaded by a string, two blocking groups being attached at both ends of the string in order to prevent de-threading [1a]. Such compounds were first prepared long ago [101, 102], but in the past they have been mostly considered as chemical curiosities. Recently, rotaxanes underwent a real revival due not only to the newly developed efficient procedures for their preparation [103–105] but also to their electro- and photochemical properties [75, 76, 106, 107] and their aptitude to undergo controlled molecular motions [108–110].

In the molecular machines previously made and investigated (see Section 8.5), a general principle is utilized: by reducing or oxidizing the copper center, from a situation corresponding to a stable complex, the system is set out of equilibrium. The relaxation process of the compound implies a large-amplitude motion which will bring the system to its new equilibrium position. In previous work on catenanes, the gliding motion of a ring within the other was studied by setting in motion either one cycle or both rings [95–97, 100].

In the rotaxanes described here, a ring is translated along a rod-like component on which it is threaded (Figure 40) [99]. The ring incorporates a bidentate chelate, and the string contains both a bidentate coordinating unit and a terdentate fragment, the string being threaded through the ring via coordination of both components to the same metal center. The system can be switched from 4-coordinate (low oxidation state) to 5-coordinate (high oxidation state) and vice versa by oxidizing or reducing the transition metal, as shown in Figure 41.

The first approach towards threaded linear systems displaying electrochemically induced molecular motions involves the synthesis of the most simple system: pseudorotaxane **Cu.29⁺**, whose ring incorporates a 2,9-diphenyl-1,10-phenanthroline moiety and whose open-chain molecular string contains two different coordination sites; and a 2,9-disubstituted-1,10 phenanthroline bidentate chelate and a terdentate tpy ligand, covalently linked by a four-carbon aliphatic chain. Copper(I) was used as a gathering and templating metal center, forcing the string to thread through the coordinating ring while generating a bis-chelate complex between the metal ion and the two phen moieties.

Figure 40. Motion of a ring on its axle.

X = small group or bulky stopper

Figure 41. Square scheme illustrating the principle of operation for the threaded compounds **Cu.29⁺**, **Cu.30⁺** or **Cu.31⁺**, reported in Figure 42. The subscripts 4 and 5 indicate the copper coordination number in each complex. The stable $\text{Cu}^{\text{I}}_{(4)}$ complex is oxidized to an intermediate tetrahedral divalent species $\text{Cu}^{\text{II}}_{(4)}$ which undergoes a rearrangement to afford the stable $\text{Cu}^{\text{II}}_{(5)}$ complex. Upon reduction, a $\text{Cu}^{\text{I}}_{(5)}$ species is formed as a transient which finally reorganizes to regenerate the starting complex. The solid circle represents Cu^{I} , and the open circle represents Cu^{II} .

The copper(I) rotaxane (**Cu.31⁺**) and its non- or partially stoppered analogues (**Cu.29⁺** and **Cu.30⁺** respectively) are shown in Figure 42.

8.6.2 Electrochemically Driven Motion

From the previously described electrochemical behavior of the catenane-type complexes [95–97], and assuming some analogous values for the redox couples $\text{Cu}^{\text{II}}_{(4)}/\text{Cu}^{\text{I}}_{(4)}$ and $\text{Cu}^{\text{II}}_{(5)}/\text{Cu}^{\text{I}}_{(5)}$, the same type of electron transfer-induced reaction is expected [111].

In the three systems **Cu.29⁺**, **Cu.30⁺**, and **Cu.31⁺**, a square scheme (as depicted in Figure 41) takes place. The electrochemical and chemical reactions are analyzed by cyclic voltammetry (CV) and controlled potential electrolysis experiments. From the CV measurements at different scan rate (from 0.005 to 2 V s⁻¹) both on the copper(I) and copper(II) species, it could be inferred that the chemical steps (motions of the ring from the phenanthroline to the terpyridine and vice-versa) are slow on the time scale of the experiments. As the two redox couples involved in these systems are separated by 0.7 V, the concentration of the species in each environment (tetra- or penta-coordination) are directly deduced from the peak intensities of the redox signals. Some voltammograms (curves a–e) obtained on different oxidation states of the rotaxane **Cu.31⁺** and at different times are displayed in Figure 43.

Figure 42. The copper(I) rotaxane and its nonstoppered analogues.

Curve (a) displays the voltammogram of a red solution of **Cu.31⁺** in degassed acetonitrile. A reversible redox wave at +0.68 V (versus SCE) is a fingerprint of the tetrahedral environment around the copper(I) atom [95–97, 100]. During the potential scan, for rates between 0.005 and 2 V s^{−1}, no redox signal corresponding to the penta-coordination could be observed. This fact evidences the high kinetic stability of the 4-coordinate copper(II) rotaxane generated at the electrode. At this stage, a controlled potential electrolysis (applied potential = +1.0 V) was performed until 1 Faraday was exchanged per mole of complex. During the electrolysis

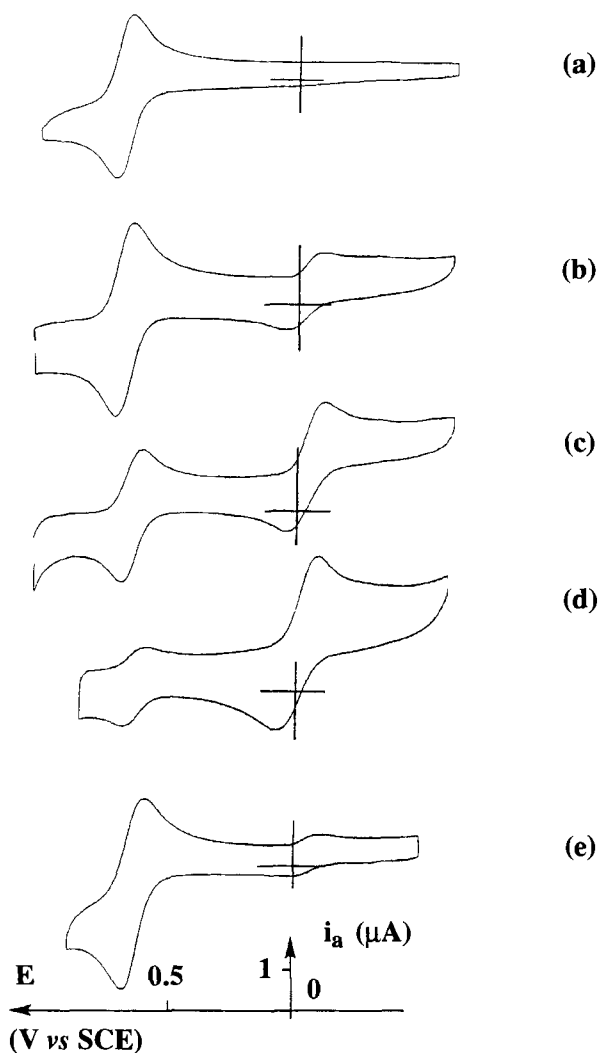

Figure 43. (a) Cyclic voltammogram of Cu.31^{2+} ; (b) after electrolysis during 1 h at +1.0 V; (c, d) evolution of Cu.31^{2+} solution with time: after 2 h (c) and after 4 h (d); (e) cyclic voltammogram immediately after electrolysis of Cu.31^{2+} solution at -0.3 V. Conditions: MeCN (0.1 M, $n\text{-Bu}_4\text{NBF}_4$), Pt electrode, scan rate (v) = 100 mV s^{-1} , 298 K.

the red color of the solution turned light green. Immediately after the coulometry, the voltammogram on the copper(II) species (curve (b)) showed the same peak at +0.68 V and an additional small reversible wave at -0.03 V. These signals are characteristic of the $\text{Cu}^{\text{II}}_{(4)}/\text{Cu}^{\text{I}}_{(4)}$ and $\text{Cu}^{\text{II}}_{(5)}/\text{Cu}^{\text{I}}_{(5)}$ couples, respectively [95–97, 100]. After several hours at room temperature, without any visible color change, the progressive disappearance of the wave at +0.68 V (4-coordinate state) and the simultaneous growth of the peak at -0.03 V (5-coordinate state) probed the coordination change around the copper (II) ion (curves (c) and (d)). The analysis of the concentration of the two different copper(II) species with time leads to a first-order rate constant of $1.5 \times 10^{-4} \text{ s}^{-1}$ for the chemical reaction $\text{Cu}^{\text{II}}_{(4)}$ giving $\text{Cu}^{\text{II}}_{(5)}$. Ac-

cording to the invariant shape of the signals with the scan rate of the copper (II) solution, it can be inferred that the rate constant for the reaction $\text{Cu}^{\text{I}}_{(5)}$ to $\text{Cu}^{\text{I}}_{(4)}$ is smaller than 10^{-2} s^{-1} . A second electrolysis at -0.3 V restores the initial red solution. The voltammogram (curve (e)) performed immediately after the reductive electrolysis displays the wave of Cu.31^+ , and is invariant with time. As all the $\text{Cu}^{\text{I}}_{(5)}$ species formed electrochemically are transformed quantitatively into $\text{Cu}^{\text{I}}_{(4)}$ species during the electrolysis, we can give a lower limit of 10^{-4} s^{-1} for the rate constant of the chemical reaction. The residual signal at -0.03 V simply reflects an incomplete electrolysis.

The behavior of the systems constituted by the unstoppered compound Cu.29^+ , or the semi-rotaxane Cu.30^+ [112], is related to the fully blocked rotaxane Cu.31^+ , i.e., the same redox couple can be observed. Some variations of peak intensities with the scan rate also indicate an acceleration of the chemical processes as compared to Cu.31^+ . However, additional signals corresponding to the species $\text{Cu}^{\text{I}}(\text{MeCN})_4^+$ ($E_{1/2} = +1.02 \text{ V}$) and $\text{Cu}^{\text{II}}_{(6)}$ (6-coordinate state, $E_{1/2} = -0.41 \text{ V}$) [95–97, 100] reveal that the dethreading process becomes significant and occurs primarily with the copper(II) species. The 6-coordinate complex evidenced by CV originates from the dethreading and coordination of the linear fragments via their tpy units to a copper center.

Of these three systems, Cu.31^+ is the most promising compound in relation with electrochemically induced molecular motions, due to the perfect chemical reversibility of the processes. Interestingly, the rates of the movements in rotaxane Cu.31^+ are very different from those measured for the related catenane Cu.25^+ (see Section 8.5) [95–97]. The conversion $\text{Cu}^{\text{II}}_{(4)}$ to $\text{Cu}^{\text{II}}_{(5)}$ is faster in Cu.31^+ than in Cu.25^+ . This difference could reflect a greater ability of $\text{Cu}^{\text{II}}_{(4)}$ in Cu.31^+ to interact with solvent molecules or anions, the copper(II) center being perhaps loosely bound to a fifth ligand which would thus stabilize intermediate states on the way to $\text{Cu}^{\text{II}}_{(5)}$.

8.6.3 Photochemically Driven Motion [99]

It is well known that Cu^{I} complexes of polypyridine ligands absorb light throughout the UV-visible spectral region, display luminescence from the lowest triplet MLCT excited state, have a reasonably long lifetime, and can play the role of electron transfer reductant [18, 49, 54, 60, 113]. This is also the case for the Cu^{I} -based chromophoric unit of rotaxane Cu.31^+ , which shows: (i) UV absorption bands due to $\pi\pi^*$ ligand-centered (LC) transitions; (ii) metal-to-ligand charge-transfer (MLCT) bands in the 400- to 700-nm spectral region (Figure 44); and (iii) a MLCT emission band with $\lambda_{\text{max}} = 785 \text{ nm}$ and $\tau = 34 \text{ ns}$ in aerated acetonitrile solution at 298 K (inset of Figure 44 and Table 18).

The spectroscopic properties and excited state properties of Cu.31^+ are similar, but not identical, to those of the analogous [2]catenane Cu.25^+ (Table 18) [95–97]. The most remarkable difference is the shorter excited state lifetime, which suggests that in the rotaxane the metal ion is less protected towards interaction with solvent molecules [29, 54g, 114]; this is probably due to the lower number of phenyl substituents onto the phenanthroline units of the rotaxane, with respect to the catenane

Figure 44. Absorption and (inset) uncorrected emission spectra in acetonitrile solution at 298 K of **Cu.31⁺** (solid line) and of the analogous, previously studied copper(1) [2]catenate **Cu.25⁺** (dashed line, Ref. [96]). The stronger absorption of the rotaxane in the UV spectral region is due to the presence of the aromatic-type stoppers.

[95–97]. In spite of the shorter excited state lifetime, we thought that it should be possible to cause the first step of the overall swinging process indicated in Figure 41, namely the conversion of **Cu.31⁺** into ***Cu.31⁺**, by light irradiation in the presence of a suitable electron acceptor (A), as described by Eqs. 22–26:

The occurrence of the excited-state electron transfer process (Eq. 24) competes with nonradiative deactivation and luminescence (Eq. 23), which is therefore a useful handle to evaluate whether Eq. 24 takes place. A necessary condition for the occurrence of Eq. 24 is, of course, that it takes place with negative free energy change. The reduction potential of the **Cu.31²⁺/*Cu.31⁺** couple can be evaluated

Table 18. Spectroscopic and kinetic parameters of the rotaxane **Cu.31⁺** and the analogous catenane **Cu.25⁺** (see Refs. [96, 99])^a

from the reduction potential of the **Cu.31²⁺/Cu.31⁺** couple (+0.68 V in acetonitrile) [112] and the energy of the ***Cu.31⁺** excited state (about 1.58 eV, as estimated from the maximum of the corrected emission band in the same solvent) by the following equation [115]:

$$E^\circ(\text{Cu.31}^{2+}/\text{*Cu.31}^+) \sim E^\circ(\text{Cu.31}^{2+}/\text{Cu.31}^+) - \xi_{0-0} = -0.90 \text{ V} \quad (27)$$

where ξ_{0-0} is the one-electron potential corresponding to the energy of the ***Cu.31⁺** excited state. This shows that even a mild oxidant should be capable of oxidizing the photoexcited ***Cu.31⁺** rotaxane (Eq. 24). As already pointed out in the previous chapter, the choice of the oxidant is not a trivial matter because other important requirements must be satisfied: (i) the oxidant should not compete with for light absorption; (ii) the reaction between ***Cu.31⁺** and the oxidant (Eq. 24) should be fast enough to compete with the intrinsic excited state decay (Eq. 23); and (iii) after reduction, the oxidant should undergo a very fast, irreversible decomposition reaction (Eq. 26) in order to prevent the occurrence of the back electron transfer reaction (Eq. 25). Such requirements are substantially met by *p*-NO₂C₆H₄CH₂Br (*p*-nitrobenzylbromide) [116–117], which was successfully used to cause photo-oxidation of the analogous catenane [96]. A Stern–Volmer analysis [118] of the quenching of the luminescence of ***Cu.31⁺** *p*-NO₂C₆H₄CH₂Br showed that the rate constant of the quenching process (Eq. 24) is $1.6 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in acetonitrile solution at 298 K, i.e., much larger than that found in the case of the catenane species

Figure 45. Principle of the photochemically and chemically triggered rearrangement of the rotaxane **Cu.31⁺**.

[96] (Table 18). This compensates for the shorter excited state lifetime of the rotaxane, and allows its photooxidation to occur in a relatively short time when a sufficiently high concentration of $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ is present in the solution. The principle of the photochemically triggered rearrangement of the rotaxane **Cu.31⁺** is shown in Figure 45.

Photochemical experiments were performed by irradiating with 464-nm light acetonitrile solutions containing 1.0×10^{-4} M **Cu.31⁺** and 1.8×10^{-2} M $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ in the presence of 0.1 M TBA(BF₄). Under these conditions, light excitation was found to cause the spectral changes shown in Figure 46, which clearly indicate the disappearance of **Cu.31⁺** and the simultaneous formation of **Cu.31²⁺** ($\text{Cu}^{\text{II}}_{(4)}$) as the only reaction product. At the end of the photoreaction, the irradiated solution was kept in the dark at 298 K. Spectrophotometric measurements showed that a slow reaction was occurring, responsible for a general decrease in absorbance, particularly in the 600- to 800-nm region (Figure 47), as expected for the transformation of **Cu.31²⁺** ($\text{Cu}^{\text{II}}_{(4)}$) into the more stable **Cu.31²⁺** ($\text{Cu}^{\text{II}}_{(5)}$) species (see Figure 45). After about 26 h, no further spectral change was observed. At this stage, the spectrum of the solution was that shown by curve (c) in Figure 47, which is that of the stable $\text{Cu}^{\text{II}}_{(5)}$ species. In order to close the cycle (Figure 45), an excess of ascorbic acid was added to the solution. A gradual, complete reappearance of the spectrum of **Cu.31⁺** ($\text{Cu}^{\text{I}}_{(4)}$) was observed, as happens when oxidation and successive reduction are carried out electrochemically. After about 8 h, the spectrum was practically coincident with the initial spectrum (Figure 47), showing that the cyclic process (Figure 45) is fully reversible even when oxidation is photo-induced and reduction is chemically induced [119].

The overall quantum yield of the photoreaction was about 3 %. Since under the experimental conditions used the fraction of ***Cu.31⁺** excited states reacting with the quencher is ~50 %, the fraction of quenching events that give rise to a permanent formation of **Cu.31²⁺** is ~6 %. Since $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ cannot quench ***Cu.31⁺** by energy transfer, the low efficiency of the photoinduced process must be attributed to a competition between back electron transfer (Eq. 25) and the irre-

Figure 46. Spectral changes caused by photoirradiation of an acetonitrile solution containing 1.0×10^{-4} M **Cu.31**⁺, 1.8×10^{-2} M *p*-NO₂C₆H₄CH₂Br, and 1.0×10^{-1} M TBA(BF₄). The isosbestic point is at 626 nm. (i) Initial spectrum; (f) final spectrum obtained after 20 min of irradiation.

Figure 47. Absorption spectra of an acetonitrile solution of: **Cu.31**⁺ containing 1.0×10^{-1} M TBA(BF₄). (a) Before light irradiation; (b) at the end of the photoreaction (about 20 min irradiation) with *p*-NO₂C₆H₄CH₂Br; (c) after subsequent 26 h in the dark; (d) 8 h after subsequent addition of an excess of ascorbic acid.

versible decomposition of the primary reduced product of $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ (Eq. 26).

The motion of the ring and of the metal ion from the bidentate to the tridentate site on the string can be carried out either electrochemically or by an oxidative photochemical process, and can be fully reversed upon chemical reduction. A comparison with the analogous catenate **Cu.25**⁺ [95–97] shows that, for **Cu.31**⁺, the excited state lifetime is shorter, the rate constant for the excited state quenching reaction by $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ is higher, and the thermal $\text{Cu}^{\text{II}}_{(4)}/\text{Cu}^{\text{II}}_{(5)}$ conversion is less clean in the absence of $\text{TBA}(\text{BF}_4)$. These results show that the metal ion is less protected from interaction with external species in the rotaxane than in the catenate, as would be expected from structural considerations. This is also in agreement with the faster and, respectively, slower rate constant observed for the $\text{Cu}^{\text{II}}_{(4)}$ to $\text{Cu}^{\text{II}}_{(5)}$ and the $\text{Cu}^{\text{I}}_{(5)}$ to $\text{Cu}^{\text{I}}_{(4)}$ conversions in the rotaxane compared to the catenane species.

8.7 Conclusions

The topological properties of the compounds discussed in this chapter are of course novel and fascinating, and this is what had originally motivated their synthesis. However, their electron transfer properties turned out later to be equally interesting—which is an additional *a posteriori* justification for their preparation. Most of the present multicomponent systems which have been made and studied in our laboratories (Strasbourg and Bologna) are obtained via a template reaction involving copper(I)bis-2,9-*diaryl*-1,10-phenanthroline as precursors. These simple complexes were at first prepared in view of their photochemical and photophysical studies, following the pioneering work of McMillin and his group [54]. It is thus not surprising that the simple or complex catenanes or knots incorporating copper(I) display interesting photochemical properties. What was less expected was the variety of photochemical behaviors, with many different energy transfer processes or multimetallic effects (control of the excited state features by another metal present in the molecule).

In addition, the original series consisting of [2]catenanes and multi-ring interlocking compounds has later been expanded to lead to porphyrin-stoppered rotaxanes. These new molecules turned out to be particularly interesting models of simple fragments of the photosynthetic reaction center, permitting an effective control of the electron transfer rate between the porphyrinic chromophores by metallating or demetallating the rotaxane complexing site. This effect provided additional evidence for the importance of superexchange in electron transfer processes.

Photoinduced electron transfer, using the presently described molecular systems, remains an interesting and promising topic—particularly in relation to charge separation and ultimately artificial photosynthesis. Nevertheless, a new area has recently emerged, which is that of multicomponent molecular sets undergoing controlled motions, under the action of an external signal. There is no doubt that this

field of research has a bright future and that, in the long term, prospective, molecular devices based on such machines, motors, and switches will be developed. Catenanes and rotaxanes are ideally suited to become the working parts of such ensembles in motion, and it is thus clear that increasingly complex and efficient such assemblies will be designed, elaborated, and studied in the future, and will function under the action of signals of various nature, whether redox, photonic, or chemical.

116. In acetonitrile solution, $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$ shows a band with $\lambda_{\text{max}} = 273\text{ nm}$ which does not interfere in the visible light absorption of $\text{Cu}^{\text{I}}\text{N}_4$. On reduction of $p\text{-NO}_2\text{C}_6\text{H}_4\text{CH}_2\text{Br}$, a benzylic radical is formed which undergoes a fast dimerization reaction. In the presence of dioxygen, the benzylic radical gives rise to a series of reaction which end with formation of benzaldehyde [117].

119. Since Cu.31^{2+} is not photosensitive and does not exhibit any long-lived excited state, the reduction step cannot be induced by light (see Refs. [95–97]).

9 Dendrimers

Alberto Juris

9.1 Introduction

Dendrimers constitute a new class of highly branched, well-defined macromolecules which are usually built with repetitive syntheses [1]. Giving an IUPAC name to these intricate structures is almost impossible, so that several trivial names have been proposed. The term dendrimer, from the Greek word for “tree”, first suggested by Tomalia et al. [2], is now the most commonly used. The geometrical similarity between trees and dendrimers is illustrated in Figure 1.

Although it is simple to understand what a dendrimer is just by looking at the beautiful chemical structures drawn in the literature, there is at present no rigorous definition of the term “dendrimer”. It is generally agreed that monodispersity is an essential characteristic of dendrimers, which are thus sets of molecules all having the same identical constitution (and thus the same molecular weight), differently from hyperbranched polymers [1], which are a mixture of different, even if chemically similar, macromolecules.

From a topological viewpoint (Figure 1b), in dendrimers one can distinguish a multifunction core unit, a number of branches growing towards the periphery, ultimately terminating with end groups. The synthetic ingenuity employed by both organic and coordination chemists has produced a great variety of different chemical structures, which in turn are attracting more and more interest to this exponentially expanding field [3, 4].

Many recent reviews report on dendrimers in general [1, 3, 5–14], or focus on more specific topics like dendrimers containing metals [15–23], or elements of groups 13, 14 and 15 [23–27], or on redox-active dendrimers [16, 19, 28, 29]. For reasons of space, it is impossible here to review all the published literature concerning dendrimers involved in electron transfer processes; only selected examples will be presented to illustrate the diversity of chemical structures and research issues that can be encountered in this field. Synthetic procedures will not be dealt with; the interested reader should refer to the original literature.

Figure 1. (a) A sketch by Leonardo da Vinci on tree branching; (b) schematic representation of a dendrimer, illustrating the basic terminology of these compounds.

9.2 Electroactive Units

As far as electron transfer properties directly involving dendrimers are concerned, it can be generally considered that these reactions may be observed whenever the macromolecular structure contains one or more units featuring redox levels at accessible potentials. The first dendrimers prepared were purely organic macromolecules, with no unit appropriate for electron transfer reactions. Later, however, the introduction of metal and organometallic complexes in the dendritic structure opened new possibilities to the chemistry of dendrimers. Indeed, the incorporated metal units exhibit important properties such as absorption and emission of visible light (relevant for the construction of antenna systems; see Volume V, Part 1, Chapter 7) and redox levels at accessible potential, which are necessary for electron transfer reactions. Successively, purely organic electroactive units have also been used to functionalize the dendrimers.

The electroactive unit may be incorporated in different positions of the dendrimer, giving rise to four prototypical kinds of functionalized structures (Figure 2a–d).

- 1) The electroactive unit is the core of the dendrimer (Figure 2a). The most commonly used units in this category are metal–polypyridine complexes and porphyrins.

Figure 2. Different arrangements of the electroactive unit(s) in dendrimers. The electroactive units are represented with a circle, and can be used as core (a), at the periphery (b); along the branches (c); or at each branching point (d).

- 2) The electroactive units are the peripheral groups (Figure 2b). These dendrimers are functionalized on their surface, and all the units are equivalent. The most common units of this type are ferrocene and metal–polypyridine complexes.
- 3) The electroactive units are located in the branches (Figure 2c). There are examples where the units are used as connectors, and cases where these units are appended to a previously synthesized structure. Also, in these kind of dendrimers all the electroactive units are equivalent.
- 4) The electroactive units are used as branching centers in the whole structure (Figure 2d). Units of this type are typically metal complexes connected by suitable bridging polypyridine ligands.

Of course, there are also dendritic structures that belong to more than one of these categories. The most significant examples of electron transfer reactions involving dendrimers containing electroactive units will be presented in Section 9.4, arranged on the basis of the electroactive unit involved. Moreover, there are examples where the dendrimer itself does not contain any electroactive unit, but is in-

stead used as a “medium” to host species involved in electron transfer reactions. Electron transfer reactions occurring in the presence of such “electroinactive” dendrimers will be reviewed in Section 9.5.

9.3 Types of Electron Transfer Reactions

Dendrimers have been insofar involved in two main types of electron transfer processes, that is electrochemical reactions and photoinduced electron transfer reactions. A few general features of these reactions are introduced in the following Sections 9.3.1 and 9.3.2.

9.3.1 Electrochemical Reactions

Many studies have been carried out on the electrochemical characterization of dendrimers. In general, the observed electrochemical behavior depends on the position occupied by the active unit(s) in the molecular structure.

When the only electroactive unit of a dendrimer is the core of the structure (Figure 2a), the most interesting problem is whether and, in case, how much the electrochemical properties (potential value, kinetic reversibility) of the core are modified by the surrounding branches.

When the electroactive units are used for peripheral functionalization (Figure 2b) and/or are located along to the branches (Figure 2c) of a dendrimer, a number of equivalent redox-active centers are present, since dendrimers are usually highly symmetric species by their own nature. The active centers may or may not interact, depending on distance and nature of the connector units. Multielectron redox processes can therefore be observed, the specific patterns of which are related to the degree of interaction among the various units.

When each branching center is an electroactive unit (Figure 2d), the electrochemical behavior is even more complex since: (i) each unit of the dendrimer is electroactive; (ii) the chemical nature of the units constituting the dendrimer may be different; (iii) chemically equivalent units can be different from the topological viewpoint; and (iv) the degree of interaction among the moieties depends on their chemical nature and distance.

9.3.2 Photoinduced Electron Transfer Reactions

This type of electron transfer reaction requires the presence of a donor–acceptor couple, and is triggered by light excitation on one of the two reaction partners. The species which absorbs the exciting light must possess appropriate photophysical properties such as a long-lived excited state at suitable energy. The quencher, on the other hand, must possess appropriate redox levels.

A classification of these photoinduced electron transfer reactions can be based on the different arrangement that the two reaction partners can assume. Thus, one can observe:

- 1) Intermolecular reactions taking place between a unit incorporated in the dendrimer structure and an external partner. This is the most commonly observed situation. Often, well-known luminescent species like Ru^{II}–polypyridine complexes [30, 31] or metallo-porphyrin species [31] are used as dendrimer cores (Figure 2a). In this case, interesting issues are how the dendritic branches can influence the photophysical properties of the core, and to which extent quencher access to the core can be prevented.
- 2) Intramolecular reactions occurring with both partners being part of the dendrimer framework. At present, this is the most uncommon case, presumably due to synthetic difficulties.
- 3) Intermolecular reactions occurring between partners that are simply hosted by an “inactive” dendrimer. Poly(amidoamine) dendrimers are most commonly used in this area, probably because they are commercially available products.

9.4 Dendrimers Containing Electroactive Units

This section presents a literature survey on dendrimers containing at least one electroactive unit. The arrangement is on the basis of the electroactive unit incorporated in the dendrimer structure. In a few cases, different electroactive units are present in the same dendrimer, so that the classification is somewhat arbitrary.

9.4.1 Ferrocene and other Sandwich Compounds

Ferrocene is the most commonly used electroactive unit for functionalization of dendrimers. Only selected examples will be illustrated here, as the related literature is very extensive [29, 32–69].

The electrochemical behavior of ferrocene is relatively simple, giving rise to a reversible monoelectronic oxidation process at a very accessible potential. Most commonly, ferrocene has been used to functionalize the periphery of dendrimers, along the scheme illustrated in Figure 2b. Dendrimers **1** [42] and **2** [55] exemplify the commonly observed electrochemical behavior:

- 1) All the ferrocene units are oxidized at the same potential, with a number of exchanged electrons equal to the number of peripheral ferrocene units, thus indicating that these units behave independently from one another.
- 2) The potential value for ferrocene oxidation shows no or only minor dependence on dendrimer generation.

- 3) The oxidized product becomes insoluble in CH_2Cl_2 and is deposited on the electrode surface, as evidenced by the presence of a cathodic stripping peak in cyclic voltammetry experiments.

In particular, dendrimer **1** is a third-generation species with 16 ferrocenyl units based on a poly(propyleneamine) framework; dendrimers of different generation, carrying 64, 32, eight, and four ferrocenyl units, behave in analogous way, with only the number of exchanged electrons being different [42]. The thermodynamics and kinetics of the adsorption of these dendrimers on the electrode surface was also investigated [49].

Compound **2** is a third-generation dendrimer based on a poly(arylether) structure and contains 24 equivalent ferrocenyl units; even in this case the potential required for ferrocene oxidation was essentially the same observed in lower-generation analogues [55].

Compound **3** and its lower-generation analogues contain a cyclotetrasiloxane core terminated with ferrocenyl peripheral units [62]. Also in this case the potential for ferrocenyl oxidation was independent from dendrimer generation, but the oxidized species remained soluble in CH_2Cl_2 .

Compound **4** contains ferrocene both as a core and as a terminal unit [45]. Cyclovoltammetric experiments in CH_2Cl_2 showed that the equivalent peripheral ferrocenyl units are reversibly oxidized at the same potential. The core unit is chemically different from the peripheral ones and, as a consequence, it is oxidized at a

different potential. The ratio between the intensity of the two waves is not exactly 1:10; this has been attributed to adsorption at the electrode surface.

Mixed-metal dendrimers have also been prepared. In compound **5**, ferrocenyl units are present at the periphery, while platinum units play the role of connectors along the branches [56]. Electrochemical oxidation in acetonitrile involves only the ferrocenyl units and confirms the presence of multiple noninteracting sites. By combining different electrochemical techniques it was possible to measure the number of ferrocene units contained in the dendrimer, thus supporting the proposed structure.

In a few cases, interaction between equivalent electroactive ferrocene units has been observed. One example is the silicon-based dendrimer **6**, containing 16 ferrocene units, which upon oxidation in CH_2Cl_2 shows two well-separated reversible

3

4

**5****6**

waves each accounting for eight electrons [47]. The same behavior was observed also in lower-generation analogues, and can be explained considering the interaction present between the two ferrocene units directly linked to the same silicon atom.

Compounds **7** and **8** can be considered as first-generation dendrimers [64]. In compound **7**, interaction of the peripheral ferrocenyl units is observed, and thus, oxidation in CH_2Cl_2 occurs in three consecutive processes, involving the exchange of two, one, and two electrons, respectively. The first process involves oxidation of two nonadjacent terminal ferrocenyls; the second is the oxidation of the central ferrocenyl, and the third corresponds to oxidation of the two remaining nonadjacent terminal units. Interestingly, in the similarly structured compound **8**, no interaction is observed between the adjacent η^6 -coordinated $\text{Cr}(\text{CO})_3$ units. Thus, oxidation of **8** gives rise to a first monoelectronic wave due to the central ferrocenyl unit, followed by a four-electron wave due to oxidation of the four chromium centers. This compound is also an example of a species where chemically distinct metal units (Fe- and Cr-based) are present, each being electroactive. Many other dendrimers incorporating different electroactive metal units can be found in Section 9.4.2.

Compounds **9–11** represent three generations of asymmetric dendrimers containing a single ferrocene unit [58]. Their electrochemical oxidation occurs in a reversible, monoelectronic wave, whose potential in CH_2Cl_2 solution is 0.63, 0.60, and 0.54 V (versus Ag/AgCl), respectively, suggesting that formation of the ferricenium ion is favored in the dendritic structure. Digital simulation of the voltammetric data allowed estimation for the first time of the heterogeneous electron transfer rate constant between dendrimers and an electrode. The values found were about 80×10^{-3} , 17×10^{-3} , and $5 \times 10^{-3} \text{ cm s}^{-1}$, respectively, for compounds **9**, **10**, and **11**, indicating that electron accessibility to the electroactive core is quickly reduced with increasing dendrimer size. Moreover, it was found that the asymmetric compound **10** exhibits an electron transfer rate greater than that of the more symmetric bis-dendritic analogue **12** [58]. The slower kinetics of **12** was attributed to the greater shielding imposed by the two dendritic branches, which preclude close approach of the ferrocene unit to the electrode surface.

The electrochemical properties of ferrocene-functionalized dendrimers have been studied also in the presence of β -cyclodextrin (β -CD), which is a well-known inclu-

sion complexation host. Poly(propyleneamine) dendrimer **1**, functionalized with 16 ferrocene units, as well its lower generation analogues, interacts with β -CD giving rise to compounds where the β -CD cavity includes the peripheral ferrocene units [46]. As a result, the solubility in water of the dendrimer increases, and the potential for ferrocene oxidation is shifted to more positive values. In the lower-generation dendrimers containing four and eight ferrocene units, only one reversible voltammetric wave is observed, indicating that each ferrocene unit is complexed by β -CD and undergoes independent monoelectronic oxidation. In contrast, with dendrimer **1** two different voltammetric waves are observed, at the potentials corresponding to oxidation of uncomplexed and complexed ferrocene units. This finding indicates that steric congestion of the surface of the higher-generation dendrimer prevents inclusion of part of the ferrocene units.

The same poly(propyleneamine) framework has been used to obtain four dendrimers functionalized with four (**13**), eight, 16, and 32 cobaltocenium units [57]. Dendrimer **13** was examined in greater detail: electrochemical reduction in aqueous solution occurs in an irreversible single-wave process transforming the cobaltocenium into cobaltocene units. As a result, the dendrimer becomes hydrophobic and deposition on the electrode takes place. Addition of β -CD prevents dendrimer precipitation, and the cyclic voltammogram exhibits a shape which is consistent with that for a reversible process. This indicates that β -CD interacts with the *reduced* form of the dendrimer, forming an inclusion complex with cobaltocene. This system is an example where electrochemical activation is required in order to trigger the host–guest interaction. As far as the higher-generation analogues are concerned, their solubility in aqueous media decreased with increasing size, so that qualitatively similar results were obtained only in the species functionalized with eight and 16 cobaltocenium units.

Compounds containing several electroactive units can be used as sensors for ion recognition. In this field, recognition of cations was achieved with compound **14** [44]. The four ferrocene units are oxidized in a single, reversible, four-electron pro-

15

cess. In tetrahydrofuran/water the potential for oxidation depends on pH, and shifts on addition of Cu^{2+} , Zn^{2+} , or Cd^{2+} , which are coordinated by the central macrocycle. At $\text{pH} < 5$ the presence of Cu^{2+} is selectively recognized.

Recognition of anions is reported in several papers. Dendrimer **15** contains 18 equivalent and independent ferrocene units in the periphery, and only a single anodic reversible wave is observed in cyclic voltammetry experiments in CH_2Cl_2 solution [53]. Progressive addition of H_2PO_4^- induces the growing of a new wave at less positive potential, while the original wave is lowered in intensity. In contrast, addition of HSO_4^- , Cl^- , and NO_3^- only produces a cathodic shift of the original wave. The lower-generation analogues, carrying nine and three peripheral ferrocene units, were also tested; a clear dendritic effect is observed, in the sense that the ion-sensing ability increases with increasing dendrimer generation. Similar dendrimers using cobalticinium as electroactive units for anion sensing have also been studied [52, 60].

The silicon-based dendrimers **16**–**18** were also investigated as anion sensors in CH_2Cl_2 solution [63]. Compound **16** was found to be a much better sensor than **17** and **18**, and is more sensitive to H_2PO_4^- and HSO_4^- , with respect to Cl^- and Br^- .

The peculiar anion-sensing ability of dendrimers **15** and **16** has been related to a synergic effect between the electrostatic interaction of the anion with the ferricinium cation and the H-bonding of the anion with the close NH group. Dendrimer **16** was also deposited on electrodes, showing anion-sensing capability similar to that observed in homogeneous solution.

Compounds **17** and **18** (and their lower-generation analogues) were studied as amperometric biosensors for glucose determination in aqueous solution, using modified carbon-paste electrodes [48]. The response to glucose was found to increase with the length of the branches, and with the presence of a greater number of ethylene groups in the branches, so that dendrimer **17** gave the best response.

A new type of core is used in dendrimer **19** functionalized with 24 $[\text{FeCp}(\eta^6\text{-arene})]^+$ units, thus obtaining a 24+ polycationic species. Cyclic voltammetry in DMF features a single reversible 24-electron reduction wave [61]. ^1H NMR spectroscopy indicates that **19** recognizes Cl^- and Br^- ions, whereas electrochemistry was in this case an ineffective technique.

An example where ferrocenyl units of a dendrimer participate to an electron transfer reaction is discussed in Section 9.4.3.

9.4.2 Metal–Polypyridine Complexes

Metal–polypyridine complexes have been used extensively as electroactive units in dendrimers [50, 51, 70–115]. For reasons of space, only representative examples are presented here.

Electrochemical investigation of dendrimers containing metal–polypyridine units shows the presence of many redox processes, as usually oxidation is a metal-centered process, while reduction is centered on the polypyridine ligands.

Compound **20** is a third-generation dendrimer based on a $[\text{Fe}(\text{tpy})_2]^{2+}$ core (tpy = 2,2':6',2''-terpyridine) surrounded by a polyether framework [93]. Electrochemical characterization in CH_2Cl_2 or THF of dendrimers of generation 0–3 indicated that the reversibility of both the metal-centered oxidation and of the tpy-

19

based reductions decreased on increasing dendrimer size. This effect is ascribed to encapsulation of the metal unit by the insulating polyether branches.

A similar organic framework was assembled around a $[\text{Ru}(\text{bpy})_3]^{2+}$ core (bpy = 2,2'-bipyridine) obtaining the three dendrimers **21**, **22**, and **23**, where the presence of many electroactive units was evidenced, giving rise to six redox processes in acetonitrile [115]. On oxidation, the reversible monoelectronic $\text{Ru}^{\text{II}} \rightarrow \text{Ru}^{\text{III}}$ wave is followed by two polyelectronic processes assigned to the dioxybenzene and oxybenzene units in the branches; in **23** the presence of a great number of these organic units gives rise to a huge unresolved wave. On reduction, three monoelectronic processes are due to the presence of the three coordinated bpy ligands. On increasing dendrimer size the processes involving the Ru–polypyridine core become more irreversible, as observed for encapsulated electroactive units.

$[\text{Ru}(\text{tpy})_2]^{2+}$ units are present in the branches of dendrimers **24** and **25**, which have identical molecular formula and are the first example of dendritic constitutional isomers [105]. These isomers feature similar solubility and decomposition temperature, whereas the electrochemical behavior (in acetonitrile), due to the four

**24**

$[\text{Ru}(\text{tpy})_2]^{2+}$ units, is different. Reduction of the two isomers evidences two processes due to the terpyridine ligands; the values of the $E_{1/2}$ for isomer **25** are slightly more negative than those of **24**. Oxidation of the Ru^{2+} ions occurs in one process for isomer **25**, whereas two waves are observed in **24**. These differences suggest the presence of different chemical environments in the two isomers, due to different internal densities and void regions.

Poly(amidoamine) dendrimers of different generations have been surface functionalized with four, eight, 16 (compound **26**), 32, and 64 $[\text{Ru}(\text{tpy})_2]^{2+}$ units [114]. One oxidation ($\text{Ru}^{\text{II}} \rightarrow \text{Ru}^{\text{III}}$) and two reduction waves (one for each tpy ligand) are observed in acetonitrile, indicating that there is no significant interaction between the $[\text{Ru}(\text{tpy})_2]^{2+}$ units, independently on dendrimer generation. After the second reduction process the dendrimer becomes neutral and deposition occurs on the electrode surface. Cyclic voltammograms show also the presence of “charge-trapping peaks”, attributed to isolated domains of the redox centers. The peak current of these charge-trapping peaks increases with dendrimer generation. The authors suggest that such an effect is not observed in ferrocene-functionalized den-

drimers because in the latter case only one redox wave is present. The analogous $[\text{Ru}(\text{bpy})_3]^{2+}$ -functionalized dendrimers were also studied, with similar results.

Metal units both in the core and in the periphery are present in dendrimers **27** and **28** [107]. In **27**, oxidation of the core occurs in acetonitrile in an irreversible process, as often observed for encapsulated redox units. This process is followed, at more positive potential, by a single reversible wave due to the six Ru-based moieties, indicating that there is no interaction between the peripheral units. In **28**, the behavior of the Ru-based units is essentially the same as in **27**, but no oxidation due to the Co-based core was evidenced. Interestingly, also chemical treatment with chlorine was ineffective in this regard.

Compound **29** can be considered as a first-generation dendrimer where each branching center is an electroactive unit [99]. In the protonated form shown, a 3-1 oxidation pattern is observed in acetonitrile: simultaneous oxidation of the three

26

Os-based units is followed by one-electron oxidation of the core Ru-based unit. Interestingly, the redox pattern can be easily reversed. Removal of the six acidic protons changes the oxidation potential of the metal ions and the oxidation pattern becomes 1-3: the core Ru unit is oxidized first, followed by oxidation of the Os units at more positive potential.

Electrochemical characterization has been performed in acetonitrile solution on a great variety of dendrimers built with metal complexes as branching centers in the whole structure [16]. An interesting example is that represented by the decametallic dendrimers **30–32**, where the metal centers are linked by bridging ligands made of two, closely connected bis-chelating units such as 2,3-dpp (2,3-dpp = 2,3-bis(2-pyridyl)pyrazine) [76, 78]. In the dendritic species, each mononuclear component brings its own redox properties, more or less affected by intercomponent inter-

27, M = Fe

28, M = Co

actions. Metal–metal and ligand–ligand interactions are noticeable for metals coordinated to the same bridging ligand and for ligands coordinated to the same metal, whereas they are negligibly small for metals or ligands that are sufficiently far apart. Since chemically equivalent non-interacting units undergo electrochemical processes at the same potential, the number of electrons lost or gained at a certain potential can be synthetically controlled.

Dendrimer **30** contains ten Ru-based units. The six peripheral Ru^{II} ions are easier to oxidize than the inner ones, because the terminal bpy ligands are better electron donors than the 2,3-dpp bridging ligands. As a result, a single six-electron wave is observed on oxidation, indicating the equivalence of the peripheral metal units. Oxidation of inner units was not observed up to +2.0 V in acetonitrile, presumably because of the large positive charge accumulated on the periphery [78].

In **31** the central unit is a Os^{II} moiety, which is easier to oxidize than the corresponding Ru^{II} moiety. As a result, on oxidation two waves are observed, accounting for one (central Os^{II} unit) and six electrons (peripheral Ru^{II} units). Compound **32** is made of an Os^{II}-based core, three Ru^{II}-based units in the intermediate positions, and six Os^{II}-based units in the peripheral positions. In this case a 6-1 pattern

**33**

is observed on oxidation: the first wave involves the six peripheral Os^{II} -based units (which contain the stronger electron-donor bpy ligand in their coordination sphere), followed by the Os^{II} -based core. Oxidation of the intermediate Ru^{II} -based units is shifted to potentials inaccessible in acetonitrile solution because of their interaction with the already oxidized core and peripheral units [78].

In larger structures, the number of equivalent units becomes huge. In the doco-sanuclear dendrimer made of an Os^{II} -based core and 21 Ru^{II} -based units, a one-electron oxidation process, assigned to the Os^{II} -based unit, is followed by a 12-electron process, due to the simultaneous oxidation of the 12 equivalent and non-interacting peripheral Ru^{II} -based units [101].

In this type of dendrimers the presence of many polypyridine ligands—each capable of several reduction processes—produces very complex reduction exchange patterns, with overlapping waves. In a smaller dendrimer as the hexametallic compound **33** it was possible to assign 26 reduction processes (in DMF at -54°C), that is all the reductions expected on the basis of the electrochemical behavior of the ligands present [110]. Oxidation of **33** up to $+4.3$ V versus SCE (in liquid SO_2) shows the presence of waves due to the metal units and also (above $+3.0$ V) to the bpy ligands, for a total of 14 electrons reversibly removed [104]. Thus, considering both cathodic and anodic processes, this compound gives rise to a redox series of 40 reversible one-electron processes, which is the largest one so far known for well-defined molecular systems.

Dendrimers based on octahedral metal complexes may be structurally not well defined because of the presence of several stereogenic centers [116]. Recently, the first examples of stereochemically pure tetrametallic Ru^{II} dendrimers have been described; compound **34** depicts the $\Delta\Lambda_3$ isomer [106]. On oxidation in acetonitrile, a three-electron wave due to the peripheral Ru^{II} units is followed by the mono-

electronic oxidation of the central metal unit. On reduction, two trielectronic waves due to the bridging ligands and to the peripheral phen ligands (phen = 1,10-phenanthroline), respectively, are followed by other unresolved multielectron processes. The stereoisomers $\Lambda\Lambda_3$ and $\Delta\Delta_3$ were also examined, and their electrochemical (and also photophysical) behavior was indistinguishable from that of the $\Delta\Lambda_3$ isomer. Thus, in these compounds the stereochemical arrangement of the various redox units appears unimportant.

Electron transfer quenching processes in dendrimers containing metal-polypyridine units has been documented only in $[\text{Ru}(\text{bpy})_3]^{2+}$ -cored species. In dendrimers **21**, **22**, and **23** the luminescent $^3\text{MLCT}$ excited state of $[\text{Ru}(\text{bpy})_3]^{2+}$ was quenched using cationic (methylviologen, MV^{2+}), neutral (tetrathiafulvalene, TTF) and anionic (anthraquinone-2,6-disulfonate) species in acetonitrile solution [115]. Quenching takes place in all cases by a dynamic mechanism. In general, the values of the quenching rate constants decrease with increasing number and size of the dendritic branches. The greatest effect was observed with MV^{2+} : the quenching rate constant decreases by more than one order of magnitude on passing from the “naked” $[\text{Ru}(\text{bpy})_3]^{2+}$ complex to dendrimer **23**. Quenching of the luminescent $[\text{Ru}(\text{bpy})_3]^{2+}$ core by dioxygen was also observed in dendrimers **21–23** [115] as well in other [100, 113] dendrimers. It is found that the lifetime of the $[\text{Ru}(\text{bpy})_3]^{2+}$ core increases on increasing dendrimer generation, indicating a progressively increasing difficulty of dioxygen to reach the Ru-based core within the dendritic structure. Diminished interaction between dioxygen and the excited $[\text{Ru}(\text{bpy})_3]^{2+}$ complex in the presence of charged dendrimers has also been observed (see Section 9.5).

9.4.3 Porphyrins and Phthalocyanins

Various dendritic porphyrins were studied as functional mimics of globular electron transfer heme proteins [117–120]. Zn porphyrin has been used as a core to build dendrimers up to the third generation (compounds **35–37**) [117, 119]. Due to the poly(ether-amide) branches these compounds are soluble in organic solvents. The first-generation compound gives rise to two reversible monoelectronic reduction (in THF) and to two reversible oxidation processes (in CH₂Cl₂). By comparison to the model core, all of these processes are assigned to the macrocycle ring, the Zn²⁺ ion being electroinactive. On increasing the dendrimer generation all the observed potentials shift to more negative values, indicating that the branches induce an increasingly electron-rich microenvironment around the core. Moreover, with increasing dendrimer size the reversibility of all the observed redox processes

decreases, becoming irreversible in the third generation species **37**, as commonly happens for encapsulated redox units.

A better model for heme proteins was obtained by replacing the inactive Zn^{2+} ion with Fe^{3+} and using triethyleneglycol monomethyl ether surface groups to yield the water-soluble dendrimers of the first (**38**) and second (**39**) generations [118, 119]. Electrochemical oxidation of **38** and **39** in water occurs in one-electron irreversible processes, due to the macrocycle ring. On reduction, a first reversible process due to the $\text{Fe}^{3+/2+}$ couple is followed by a second irreversible wave due to the $\text{Fe}^{2+/1+}$ couple. Interestingly, whereas the potential for the $\text{Fe}^{2+/1+}$ couple is the same for the two dendrimers, the potential for the $\text{Fe}^{3+/2+}$ couple shifts about 420 mV towards more positive values on passing from **38** to **39**. This difference was attributed to the different environment around the iron core: whereas in the smaller dendrimer **38** the Fe^{3+} ion can be easily solvated by water, in **39** the denser dendritic structure reduces water access to Fe^{3+} , which is thus more destabilized relative to Fe^{2+} .

Very recently the iron porphyrin core has been modified in order to control the axial ligation to the iron center by means of two imidazoles tethered to the porphyrin ring [120]. The generation zero (**40**), one (**41**), and two (**42**) dendrimers have been prepared and the redox behavior of the $\text{Fe}^{3+/2+}$ couple has been examined in three solvents of increasing polarity, namely CH_2Cl_2 , acetonitrile, and water. The redox potential of the $\text{Fe}^{3+/2+}$ couple becomes more positive with increasing dendrimer generation, the process being reversible in all cases. For dendrimers **40** and

41 the potential value is solvent-dependent, increasing with increasing solvent polarity. Interestingly, for the larger dendrimer **42** the potential value is the same in all of the three solvents, indicating that the dendritic branches are dense enough to prevent solvent access to the iron core, which thus experiences a unique local microenvironment independently from the solvent. This shielding behavior is similar to that exercised by the peptide shell around the $\text{Fe}^{3+/2+}$ couple in cytochromes.

A compound where a porphyrin unit is linked to fullerene is described in Section 9.4.5.

Zinc porphyrin has been also functionalized with a benzyl ether framework to obtain the dendrimers **43–46**, corresponding to generations 1–4 [121]. Electrochemical investigation was used to assess the rate of electron transfer between the electrode surface and the redox-active core. The smaller dendrimer **43** features four monoelectronic processes: the two oxidation waves (in CH_2Cl_2) and the first reduction wave (in DMF) are reversible, whereas the second reduction process is partially irreversible. Even in these compounds on increasing dendrimer generation the redox processes become more irreversible, complete irreversibility being reached with the third-generation species **45**. This effect is ascribed to the presence of the relatively rigid dendritic branches that hinder the approach of the core to the electrode surface.

Similar behavior has been very recently observed in cobalt phthalocyanines bearing dendritic substituents [122]. In **47**, Co^{II} is oxidized in methanol in a mono-electronic reversible wave, whereas in **48** no clear oxidative wave is observed, suggesting that the electroactive core is encapsulated in the dendritic structure. The ability of the Co-phthalocyanine core of **47** and **48** to catalyze oxidation of 2-mercaptoethanol in the presence of oxygen was also investigated. The two compounds exhibit similar catalytic activity, indicating that the dendritic structure does not hinder penetration of small molecules; **48** showed, however, an enhanced catalytic stability which was ascribed to the encapsulation of the core.

A phthalocyanine core was functionalized with four, eight, and 16 ferrocenyl units (compounds **49–51**) [67]. Cyclic voltammetry experiments in DMF or CH_2Cl_2 showed the presence of many quasi-reversible waves. All the ferrocenyl units behave independently, giving rise in all three compounds to a single oxidation wave, which is accompanied by one or two oxidation and by two or three reduction processes due to the phthalocyanine π -system. For **51**, the presence of a stripping peak indicates precipitation of the oxidized product in CH_2Cl_2 , as often observed in ferrocene-functionalized dendrimers (see Section 9.4.1).

Photoinduced electron transfer quenching of a porphyrin-cored dendrimer was first reported in compound **52**, where the fluorescence of the Zn core is quenched in acetonitrile by vitamin K_3 (2-methyl-1,4-naphthoquinone) [123].

Later, generation 2 and 4 (**53**) water-soluble analogues were obtained [124]. In **53**, photophysical investigation showed that long-range photoinduced electron transfer *through* the dendrimer framework occurs between the encapsulated core and methylviologen molecules electrostatically interacting with the periphery of the dendrimer. In the generation 2 compound, on the other hand, quenching by methylviologen is much more efficient, because direct access to the core is possible.

A similar quenching by methylviologen through the dendrimer architecture was also observed in the Zn-phthalocyanine-cored dendrimer **54** [125].

**49****50**

Electron transfer quenching of the excited metalloporphyrin core in compounds **43–46** was investigated in DMF using benzylviologen as electron acceptor [121]. The estimated electron transfer rate constants are similar in the four dendrimers, indicating that small molecules have no difficulties in approaching the porphyrin core. Thus, these porphyrin dendrimers may potentially be employed as catalysts.

The fluorescence of the zinc-phthalocyanine core in dendrimer **49** is completely quenched [67]. On the basis of energetic considerations, this quenching process was attributed to electron transfer from the connected ferrocenyl units to the excited phthalocyanine core. The photophysical behavior of **50** and **51** was not mentioned.

**51**

52, R = $-\text{O}-\text{CH}_3$ 53, R = $-\text{COOK}$

Two series of Zn-phthalocyanine dendrimers with aryl-ether branches were obtained as mixtures of constitutional isomers. Generation 0, 1, and 2 (dendrimer **55**) species, terminated with ester groups, are soluble in organic solvents, while the species terminated with carboxylate units (e.g., **56**), are soluble in water [126]. Photoinduced electron transfer quenching of the fluorescent core of the ester-terminated dendrimers was investigated using anthraquinone as electron acceptor. The quenching occurs through a dynamic mechanism, and the rate of the electron transfer process decreases with growing dendrimer size. The fluorescence of the core of the water-soluble series was quenched with anionic (picrate anion), and cationic (5,10,15,20-tetrakis(1-methyl-4-pyridyl)porphyrin) electron acceptors. With the picrate quencher, a sharp decrease of the bimolecular electron transfer rate constant is observed on increasing dendrimer generation, **56** being virtually unquenched. This behavior was ascribed to the highly negative dendrimer surface that repels electrostatically the picrate anion. In contrast, using the cationic quencher, the electrostatic interaction with the dendrimer results in a very efficient quenching through a static mechanism.

9.4.4 Tetrathiafulvalene

The tetrathiafulvalene (TTF) unit received attention owing to its possibility of being oxidized in two reversible monoelectronic steps at very accessible potential. Three generations of polyaryl-ester dendrimers containing three, six, and 12 (compound **57**) TTF units at the periphery were prepared, and their redox behavior examined in acetonitrile solution [127]. In each of the three dendrimers the TTF units are oxidized at the same potential in two multielectronic processes, indicating that they are noninteracting. Chemical oxidation of the TTF units in the three dendrimers was also achieved using iodine. Analogous results were obtained in other dendritic structures [128, 129].

The TTF unit was used also as core in dendrimers **58** and **59**, containing respectively four and 12 additional TTF units along the branches [130]. In both com-

**55**, R = COOC₅H₁₁**56**, R = COONa

pounds electrochemical oxidation in benzonitrile features the typical two redox reversible processes due to each TTF unit, indicating that all of these units behave independently, irrespective of their topological position. By applying for the first time to redox-active dendrimers the thin-layer cyclic voltammetry (TLCV) technique, it was also possible to measure the number of electrons exchanged in each oxidation wave, the result being five and about 13 for **58** and **59**, respectively, in CH₂Cl₂ solution. Thus, each TTF unit is oxidized simultaneously in both dendrimers.

Asymmetric functionalization was achieved in the two dendrimers **60** and **61**, which contain two branches terminated with electron-donor TTF units and one branch terminated with electron-acceptor anthraquinone (AQ) units [131]. Cyclic voltammetric investigation in acetonitrile showed that each of these electroactive units are noninteracting, giving rise to two waves on oxidation (due to TTF) and to two waves on reduction (due to AQ). The number of electrons exchanged in each of

57

these reversible processes corresponds to the number of redox-active units present. Thus, these compounds can be switched reversibly between cationic and anionic states under electrochemical control; for example **60** can be switched between the +8, +4, 0, -2, and -4 states.

9.4.5 Fullerene

Fullerene has also been incorporated in redox-active dendrimers. In **62** the C_{60} unit has been modified by connecting a single polyaryl-ether dendritic branch [132]. Electrochemical reduction in CH_2Cl_2 of **62** features three reversible waves, which occur at a potential more negative than that of the free C_{60} molecule. This shift was ascribed to an insulating effect on the connected dendritic structure.

Starting from the fullerene-porphyrin dyad **63**, dendrimers **64** and **65** (generations 1 and 2) were obtained adding five dendritic branches to the remaining octahedral positions of C_{60} [133]. The π -system of fullerene is disrupted by the

61

60

62

added units, so that its reduction in CH_2Cl_2 occurs in a single irreversible process at more negative potential with respect to the unsubstituted C_{60} . A further reduction process is observed, due to the porphyrin ring. On oxidation, two processes occur, also attributed to the Zn-porphyrin unit. Only the reduction waves are dendrimer generation-dependent, shifting to more negative potential on increasing dendrimer size. Quenching experiments of the Zn-porphyrin fluorescence were also performed. In dyad **63**, electron transfer quenching is observed, the C_{60} acting as electron acceptor. In contrast, in dendrimers **64** and **65**, no electron transfer occurs, due to the fact that the electron-accepting properties of C_{60} are greatly reduced in these species, as indicated by the electrochemical data.

9.4.6 Naphthalene Diimide

The naphthalene diimide electroactive unit was used to functionalize poly(amidoamine) dendrimers up to the sixth generation [134]. Compound **66** illustrates the first-generation dendrimer, containing six peripheral diimide units; in the sixth generation dendrimer the peripheral units number 192. Cyclic voltamme-

66

try in aqueous or DMF solution identifies two reduction processes, whose potential is independent from the dendrimer generation, while coulometry experiments indicate the exchange of one electron per imide group in both waves. The first reduction wave is very broad, indicating that the diimide units are not independent, probably because of π -stacking aggregation.

Generations 1–5 of dendrimers such as **66** were reduced with sodium dithionite in water or formamide to yield the diimide anion radicals [135, 136]. These reduced species were used to produce films that constitute the first example of electrically conducting dendrimers.

Dendrimer **67** contains two naphthalene diimide electroactive units in the core [137]. Electrochemical investigation in DMF showed the presence of two reversible bielectronic reduction processes at the potential typically featured by other naphthalene diimide-containing compounds. Thus, the two units behave independently and can be readily accessed from the electrode surface. The lack of encapsulating

**68**

effect is ascribed to the structure of the core, which is rather long and rigid, and cannot be surrounded by the dendritic branches.

9.4.7 Triaryl Amines

Cyclic voltammetry in THF of the triarylamine-based dendrimer **68** indicated the presence of at least four unresolved waves, giving rise to delocalized radical cations [138].

Dendrimer **69** contains different electroactive units arranged in order to obtain a radial redox gradient [139]. Three *p*-phenylenediamine units are located around the benzene core; these moieties are oxidized in two reversible waves in CH_2Cl_2 , corresponding to one- and two-electron processes. At more positive potential a reversible three-electron wave is observed, and assigned to the uncoupled peripheral arylamino groups. Further oxidation processes were also observed, but not discussed. Chemical oxidation of **69** was accomplished with NOPF_6 , and the self-exchange electron transfer rate between the neutral/cation phenylenediamine couple was measured in mixtures of 69/69^+ . The value obtained, $k_{\text{et}} = 1.8 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ in CDCl_3 at 25°C , is 10^3 – 10^4 times lower than the self-exchange rate in model *p*-phenylenediamine compounds, indicating that the dendritic structure imparts a significant kinetic barrier to the intermolecular electron transfer exchange.

Several articles have addressed the possibility of using dendritic molecules as electroluminescent materials in organic light-emitting diodes (LEDs) [140–148]. For example, compound **70** works as an excellent hole transport material, and has been incorporated into multilayer devices that exhibit high luminance efficiency and significant thermal stability [140, 141, 144].

Another compound used in multilayer organic LEDs is dendrimer **71** [143], the electrochemical oxidation of this molecule having also been investigated in CH_2Cl_2 solution. A series of six reversible waves is observed, accounting for a total of nine

**71**

electrons removed, thus indicating that multiple electrons can be exchanged at the same potential. Another example of dendrimer used in LED devices is compound **90** (see Section 9.4.8).

9.4.8 Other Electroactive Units

Electroactive *palladium units* were incorporated in a series of dendrimers starting from a phosphorus–ethylene framework [149]. Compounds **72** and **73** depict two of the largest structures prepared. Cyclic voltammetry in DMF of **72** features a quasi-reversible cathodic wave assigned to two-electron reduction occurring at each palladium atom. In contrast, for **73** the cyclic voltammogram shows ill-defined, broad waves. Interestingly, the acetonitrile-containing dendrimers such as **73** were found to catalyze the electrochemical reduction of CO_2 to CO , with rates and selectivities similar to those seen with analogous monometallic complexes.

**72**, R = PEt_3 **73**, R = CH_3CN

Aryl-ether-based dendrons were used as stoppers in a series of rotaxanes containing one to three *bipyridinium units* surrounded by polyether macrocycles (compounds **74–76**) [150]. Electrochemical investigation in acetonitrile shows that a first reversible cathodic wave is due to the bipyridinium units, which are all reduced simultaneously and independently at the same potential. Electrode adsorption problems prevented accurate measurements for a second reduction process, also due to the bipyridinium units. On oxidation, two not fully reversible processes are observed, involving both the polyether macrocycle surrounding the bipyridinium units and the dioxybenzene units of the dendritic stoppers.

The inorganic *iron–sulphur cluster* $[\text{Fe}_4\text{S}_4(\text{SR})_4]^{2-}$ was used as a core to build the polyaryl-ether dendrimers **77–80**, corresponding to generations 1–4, respectively [151, 152]. The iron–sulphur core is electroactive, giving rise to a quasi-reversible monoelectronic reduction process in DMF solution. On increasing dendrimer generation the reduction potential moves to more negative values and the electron exchange becomes more irreversible, indicating that the electroactive center is progressively encapsulated by the dendritic structure.

Very few cases exist where the electroactive units are located along the branches of the dendrimer. One example is represented by compound **81**, where four *anthraquinonoid units* are located near the core, with connected dendrons pointing outside [153]. Cyclic voltammetry experiments in acetonitrile showed that the four electroactive units are essentially noninteracting. The increasing irreversibility of the reduction waves with increasing dendron generation indicates a progressive encapsulation of the electroactive units.

A *tetrathienylenevinylene* core was used to obtain the dendrimers **82–84** (generations 1–3, respectively) [154]. Oxidation in CH_2Cl_2 of the electroactive core occurs in two reversible monoelectronic processes, with identical cyclovoltammetric waves for compounds **82–84**. The absence of any effect of the dendrimer generation indicates that the electroactive core is not encapsulated in the dendritic structure, as is commonly observed. The authors suggest that in this case the redox-active core is too long to be completely surrounded by the dendritic branches.

Very recently, poly(amidoamine) dendrimers were surface-functionalized with four, eight (**85**), 16, and 32 *nitroxyl radical units* [155]. In all these dendrimers electrochemical oxidation in acetonitrile of the appended radical units occurs at the same potential in a single reversible process, the number of exchanged electrons being equal to the number of units present. Thus, all the nitroxyl radical fragments in the dendrimer behave independently and are accessible from the electrode surface.

Dendritic branches of generations 1–3 (**86**) were built using aryl imides and a [5]helicene derivative [156]. In the three compounds a first reversible reduction in DMF, attributed to the *anhydride–imide* unit, is followed by a second process, assigned to the *o-terphenyl* moieties. The number of exchanged electrons was not measured. The second process, which is irreversible in the generation 1 species, becomes reversible in compounds of generations 2 and 3, suggesting that in the larger dendrimers the reduced species is stabilized by interaction with other *o-terphenyl* units.

The first investigation on photoinduced intramolecular electron transfer between units covalently attached to a dendritic framework was performed on a series of

74, $n = 0$; **75**, $n = 1$; **76**, $n = 2$

**81**

poly(arylether) dendrimers [157]. Compound **87** illustrates one of the largest dendrimers investigated. The peripheral excited states of *naphthyl* or *pyrenyl* chromophores are quenched by *triethylamino* or (*dimethylamino*)*phenoxy* groups, which play the role of electron donors. The efficiency of the process is function of dendrimer size and of solvent polarity (CH_2Cl_2 , THF, and acetonitrile were tested). As substantial electronic coupling exists within the dendrimer between chromophores and quenchers, these compounds appear promising as light-energy harvesters (see Volume V, Part 1, Chapter 7). Bimolecular quenching experiments were also performed using amines that were not connected to the dendrimer structure.

Intramolecular charge transfer interaction was investigated between *diphenylacetylene* electron donor groups and the *p*-*dimethoxybenzene* moiety in dendrimers of generations 1–6 [158]. Compound **88** illustrates the second generation species. Anomalous shifts of the emission spectrum (depending on the dendrimer generation and on the solvent used) suggested that a sudden change on size and shape of the dendrimer occurs, starting from the fifth-generation species.

Poly(propyleneamine) dendrimers of generations 1 and 4 (**89**) functionalized with azobenzene groups were investigated as hosts for eosin Y (eosin = 2',4',5',7'-tetrabromofluorescein dianion) in DMF solution [159]. The peripheral azobenzene groups can be switched by light excitation from the *E* to the *Z* form. The fluorescent excited state of eosin is reductively quenched by the *tertiary amine* units present in the dendrimer structure. This electron transfer quenching takes place with a static

85

mechanism, indicating that the quenchable eosin molecules are hosted inside the dendrimer. It was also found that eosin is quenched (and thus, hosted) more effectively when the peripheral azobenzene groups are in the *Z* form.

Various generations of dendrimers based on *phenylenevinylene* units were incorporated into LED structures [145, 148]. Compound **90** depicts a second-generation species. The efficiency of the LED device depends on dendrimer generation, the maximum in efficiency being reached with the second-generation dendrimer **90**. By substituting the distyrylbenzene core with porphyrin or anthracene units, it is also possible to tune the electroluminescence emission in the blue, red, and green regions of the spectrum [146]. Other dendrimers used in LED fabrication can be found in Section 9.4.7.

Finally, the ability of dendrimers to mediate electron transfer reactions has also been examined from a theoretical viewpoint [160, 161]. The electronic coupling in idealized dendrimers is predicted to be simply a function of the number of branches occurring at each branching point. The peculiar connectivity within the dendritic structure gives rise to hot and cold spots for electron transfer on the surface of the dendrimer—a behavior similar to that expected for the surface of proteins.

86

87

88

89

9.5 Electroinactive Dendrimers

This section describes cases where the dendrimer itself does not contain any electroactive unit, but is instead used as a “medium” to host species involved in electron transfer reactions.

Various generations of poly(amidoamine) dendrimers have been surface-terminated with carboxylate groups to investigate the effect of the negatively charged surface on the reactivity of small cationic molecules [162–167]. Compound **91** exemplifies a 2.5-generation dendrimer (this is a half-generation species on the basis of the dendrimer nomenclature). The photophysical properties of $[\text{Ru}(\text{bpy})_3]^{2+}$ or $[\text{Ru}(\text{phen})_3]^{2+}$ were investigated in the presence of these negatively charged dendrimers. In air-equilibrated aqueous solution, the excited Ru complex is quenched by oxygen [162, 163, 165, 167]. It is observed that the lifetime of the excited Ru complex increases on increasing dendrimer generation; this behavior has been related to a decrease of oxygen concentration near the dendrimer’s surface. Note that, by contrast, in dendrimers containing a $[\text{Ru}(\text{bpy})_3]^{2+}$ core dioxygen quenching is prevented because the branches encapsulate the luminescent complex (see Section 9.4.2).

Photoinduced electron transfer between photoexcited $[\text{Ru}(\text{bpy})_3]^{2+}$ (or $[\text{Ru}(\text{phen})_3]^{2+}$) and a variety of quenchers was also investigated in aqueous solution [162–167]. Different results were obtained depending on dendrimer generation. For example, with methylviologen as quencher in the presence of smaller poly(amidoamine) dendrimers (up to generation 2.5), the electron transfer process occurs with a bimolecular mechanism where the excited Ru complex is quenched outside the

dendrimer surface. This is consistent with the notion that these dendrimers possess a open-surface structure, and their size is too small to host on their surface the two reaction partners. With higher generation (>3.5) dendrimers the quenching mechanism becomes monomolecular, indicating that the electron transfer quenching occurs while both partners are adsorbed on the dendrimer's surface. This behavior is related to the more closed and spherical surface structure of these later-generation dendrimers. Experiments performed using other cationic or anionic quenchers such as $[\text{Co}(\text{phen})_3]^{3+}$ [165, 166], and $[\text{Fe}(\text{CN})_6]^{4-}$ [162–164] substantiated this picture. Moreover, the photophysical properties of *anionic* Ru–polypyridine complexes in the presence of positively charged poly(amidoamine) dendrimers (terminated with protonated amine groups) were also studied, with similar results [168]. A statistical analysis of these quenching processes occurring at the surface of dendrimers has also been performed [166].

Poly(amidoamine) dendrimers such as **91**, which differ only in the presence of an ethylenediamine (instead of ammonia) core, were used to host the electron transfer reaction between photoexcited polycyclic aromatic hydrocarbons (PAHs) and nitromethane [169]. Quenching studies in aqueous solution indicate that the PAHs associate with the dendrimer, residing in the interior region, far from the charged surface. It was also found that within the dendrimer structure, nitromethane quenches alternant PAHs, while nonalternant PAHs are not quenched. This selective behavior of nitromethane parallels that commonly observed in solution, while in the presence of traditional micelles both classes of PAHs are quenched by nitromethane.

Poly(amidoamine) dendrimers of the fourth generation with $-\text{OH}$ terminal groups were used as templates to produce stable metal nanoparticles [170–172]. The dendrimers (in aqueous solution) are first loaded with a predetermined amount of Cu^{2+} or Pt^{2+} metal ions; following chemical reduction, metal nanoparticles are formed inside the dendrimer structure, where they are protected from agglomeration. This procedure permits both particle stability and control over particle size. Dendrimers containing Pt metal clusters were also attached to gold electrodes, and were found to be active as electrocatalysts for O_2 reduction [172]. This demonstrates that the nanoparticles inside the dendrimer can mediate electron transfer processes between the electrode surface and reactants in solution.

Functionalized gold electrodes were prepared by adding a monolayer of fourth-generation poly(amidoamine) dendrimer terminated with amine groups [173]. The response of these electrodes was examined in aqueous solution with the probe molecules $[\text{Ru}(\text{NH}_3)_6]^{3+}$ and $[\text{Fe}(\text{CN})_6]^{4-}$. At low pH values, when the dendrimer amine groups are protonated, only the $[\text{Fe}(\text{CN})_6]^{4-}$ probe can penetrate through the dendrimer structure to undergo electron exchange with the electrode surface. At higher pH values, when the amine groups are fully deprotonated, both probes can undergo electron transfer. These dendrimers can thus act as molecular gates, allowing selective mass transfer through the dendrimer. Similar pH-dependent behavior was also observed when grafting onto gold surfaces composite films formed from multilayers of amine-terminated dendrimers and an amphoteric random coil polymer [174]. In this case, depending on pH, selective access to the electrode surface can be obtained both for cationic and anionic probe molecules.

Poly(amidoamine) dendrimers of generations 2, 4, 6, and 8 have been tested as

91

adhesion promoters between vapor-deposited Au films and glass or other Si-based substrates [175]. The best adhesion properties are obtained with the higher generation dendrimer, which has a total of 1024 primary amine groups on the surface. The stability of electrodes built with glass/dendrimer/Au films was examined using $[\text{Ru}(\text{NH}_3)_6]^{3+}$ as redox probe in aqueous solution. After 4 h of continuous cycling the system did not show any performance reduction, indicating that electrodes built with this technique may be suitable for many common applications.

9.6 Concluding Remarks

This chapter on electron transfer reactions of dendrimers which, for reasons of space is not exhaustive, clearly indicates that, to date, two main topics have been investigated, namely electrochemical reactions and photoinduced electron transfer reactions.

As far as their electrochemical behavior is concerned, several interesting dendrimers have been synthesized, but in most cases these properties have not been investigated in great detail. Nevertheless, a few carefully performed studies have shown that electrochemistry is a powerful technique to: (i) elucidate the structure (and purity) of the dendrimers—a task that is not at all easy with these highly branched (and sometimes highly charged) compounds; (ii) evaluate the degree of electronic interaction of the various, chemically and/or topologically equivalent or nonequivalent moieties of a dendrimer; and (iii) study the endo- and exoreceptor capabilities of the dendrimers. Detailed electrochemical studies on dendrimers with an electroactive core promise to be rather useful in modeling natural electroactive species, and in investigating the problem of insulating such a unit from the electrode surface. Moreover, the importance of dendrimers as species capable of performing multielectron redox reactions has been highlighted since 1995 [176].

Photoinduced electron transfer studies have been performed in a more limited number of cases, due to the fact that the simultaneous presence of *two* reaction partners with appropriate characteristics is necessary. The study of suitably functionalized dendrimers can furnish information on the accessibility of the inner shell or core to external reagents (such as molecular oxygen or other small molecules) and on interchromophoric interactions within the dendritic structures. “Electroinactive” dendrimers can also be important in regulating the electron transfer reactions between hosted partners; in this sense dendrimers may also constitute a peculiar medium to investigate electron transfer reactions in restricted spaces.

Various recent papers have discussed possible applications of dendrimers [3, 4, 11, 14, 20, 23]. From the point of view of electron transfer, the interest in highly branched structures such as dendrimers is related not so much to their size, but rather to the presence of different components. In fact, an ordered array of different components can generate valuable properties, such as the presence of cavities with different size, surfaces with specific functions, gradients for photoinduced energy and electron transfer, and sites for multielectron transfer catalysis. At this point it is perhaps worth summarizing the practical applications of dendrimers encountered in this chapter. Dendrimers have already been used: (i) in catalytic processes [122, 149, 172]; (ii) in the functionalization of electrodes [48, 63, 172–175] which can also work as sensors [44, 48, 63]; (iii) in the fabrication of nanoparticles [170–172]; and (iv) in other devices such as LEDs [140–148] and molecular gates [173, 174]. Moreover, as many different exciting applications will certainly be added to this list in the future, it is easy to foresee a remarkable expansion in dendrimer related research.

Part 1

Catalysis of Electron Transfer

1 Fundamental Concepts of Catalysis in Electron Transfer

Shunichi Fukuzumi

1.1 Introduction

Catalysis is the most important concept to control any kind of chemical reaction, including enzymatic reactions in biological systems [1–4], contributing greatly to world industrial chemical output [5–11]. Among many types of chemical reactions, an electron transfer reaction is the most fundamental, since the electron is the minimal unit of the change in chemical reactions and any chemical bond is formed via electrons. The importance of electron transfer processes has been recognized in nearly every subdiscipline of chemistry, i.e., not only inorganic chemistry but also organic and organometallic chemistry [12–26]. Electron transfer processes often play an important role as a key elementary step in a variety of catalytic cycles [27–37]. This type of catalysis is called electron transfer catalysis (ETC) and it is characterized by a classical catalytic cycle which involves one or more electron transfer processes. In such cases, an electron transfer reaction often initiates a chain reaction in which the propagation step also involves an electron transfer process as shown in Scheme 1 [24–32].

Compared with electron transfer catalysis, which has been undergoing extensive exploration and expansion [24–34], catalysis of electron transfer reactions themselves has yet to emerge as an identifiable field of study. The conceptual lack of catalysis in electron transfer reactions seems to stem from a general belief that there may be no need for catalysis to accelerate further the electron transfer reaction, which is generally fast enough in a practical sense. This is largely true for reversible electron transfer reactions in which electron transfer occurs only when the free energy change of electron transfer is negative, i.e., the electron transfer is exergonic. If the electron transfer is endergonic, no net electron transfer would occur because of facile back electron transfer to regenerate the reactant pair. However, numerous chemical reactions, previously formulated by ‘movements of electron pairs’, are now understood as processes in which an initial electron transfer from a nucleophile (reductant) to an electrophile (oxidant) produces a radical ion pair, which leads to

the final products via the follow-up steps involving cleavage and formation of chemical bonds [12–23, 38–42]. The follow-up steps are usually sufficiently rapid to render the initial electron transfer the rate-determining step in an overall *irreversible* transformation as shown in Figure 1 [42]. In such a case, catalysis in the rate-determining electron transfer step, which is usually endergonic ($\Delta G_{\text{et}}^{\circ} > 0$) and thereby thermodynamically unfavorable, would play an essential role in accelerating the overall redox reaction.

Since photoexcitation induces significant enhancement of the reactivity of electron transfer, photochemical reactions via photoinduced electron transfer have been explored in homogeneous systems [43–52]. On the other hand, the term ‘photocatalysis’ has usually been used in heterogeneous systems involving photoinduced electron transfer across the gas–solid or liquid–solid interface [53–60]. Photocatalysis has been extensively studied using a semiconductor particle as a photocatalyst [53–60]. Photocatalysis is initiated by the absorption of a band gap photon

Figure 1. Energy diagram of irreversible electron transfer from an electron donor (D) to an acceptor (A).

at or near the surface of a semiconductor particle. This important field is covered in another chapter in this section [61].

Photochemical reactions involving photo-excited states can also be catalyzed as well as the thermal reactions of ground states. However, the lifetimes of excited states are usually very short, particularly for the singlet excited states, and accordingly reactions of the excited state should be fast enough to compete with the decay of the excited state to the ground state (typically the lifetime is 10^{-6} – 10^{-12} s). Hence there seems to be little chance of catalysis to accelerate the reactions of excited states, which are already fast. There are many cases, however, such that photochemical reactions can be accelerated by some added substances which act as catalysts in the photochemical reactions [62–65]. Photoinduced electron transfer reactions can also be accelerated by the presence of an appropriate catalyst [52].

This chapter is intended to focus on catalysis in both thermal and photoinduced electron transfer reactions between electron donors and acceptors by investigating the effects of an appropriate substance that can reduce the activation barrier of electron transfer reactions. It is commonly believed that a catalyst affects the rate of reaction but not the point of equilibrium of the reaction. Thus, a substance is said to act as a catalyst in a reaction when it appears in the rate equation but not in the stoichiometric equation. However, autocatalysis involves a product acting as a catalyst. In this chapter, a catalyst is simply defined as a substance which affects the rate of reaction. This is an unambiguous classification, albeit not universally accepted, including a variety of terms such as catalyzed, sensitized, promoted, accelerated, enhanced, stimulated, induced, and assisted. Both thermal and photochemical redox reactions which would otherwise be unlikely to occur are made possible to proceed efficiently by the catalysis in the electron transfer steps. First, factors that accelerate rates of electron transfer are summarized and then each mechanistic viability is described by showing a number of examples of both thermal and photochemical reactions that involve catalyzed electron transfer processes as the rate-determining steps. Catalytic reactions which involve uncatalyzed electron transfer steps are described in other chapters in this section [66–68].

1.2 Factors to Accelerate Rates of Electron Transfer

According to the Marcus theory [69–71], the rate constants (k_{et}) of electron transfer are determined by the free energy change of electron transfer ($\Delta G^\circ_{\text{et}}$) and the reorganization energy associated with the electron transfer (λ) as given by:

$$k_{\text{et}} = \kappa Z \exp[-(\Delta G^\circ_{\text{et}} + \lambda)^2 / 4\lambda RT] \quad (1)$$

where κ is the probability for the electron transfer to occur normalized to the number of times the molecule acquires the correct nuclear configuration to pass through the intersection of the potential energy surfaces of the reactants and products, Z is the collision frequency in an intermolecular electron transfer reaction or

Scheme 2.

the vibrational frequency in an intramolecular electron transfer and λ is the nuclear reorganization energy including the solvent reorganization associated with electron transfer [69–71]. The κ value is taken as unity for an adiabatic process in solution when the interaction energy at the intersection is so large that formation of transition state can lead almost inevitably to the product.

As shown in Scheme 2, an electron is transferred from an electron donor (D) to an acceptor (A) instantaneously according to the Franck–Condon principle when the reactant pair (D – A) is activated to reach the nuclear configurations which include the solvation, where the energy before and after the electron transfer is the same. Figure 2 shows the dependence of $\log k_{\text{et}}$ on $\Delta G^{\circ}_{\text{et}}$ based on Eq. 1. The k_{et} value increases with decreasing (a) $\Delta G^{\circ}_{\text{et}}$ or/and (b) λ (Figure 2). Thus, in order to accelerate the rate of electron transfer, the $\Delta G^{\circ}_{\text{et}}$ or/and λ values should be decreased.

If a catalyst (C) which can interact with one of the products of electron transfer (e.g., $A^{\bullet -}$ in Scheme 2) is introduced into the D – A system, the factors to control the rate of electron transfer, $\Delta G^{\circ}_{\text{et}}$ and λ , may be altered. The $\Delta G^{\circ}_{\text{et}}$ value is shifted in the negative direction when the activation barrier of electron transfer is reduced to accelerate the rates of electron transfer as shown in Scheme 2, where C forms a complex with $A^{\bullet -}$. Since most organic compounds such as π acceptors in particular have small reorganization energies, the change of redox potentials due to the interaction of the corresponding radical anions with C may be the main factor to accelerate the rates of electron transfer. Thus, any catalyst C that can stabilize the products of electron transfer thermodynamically by complexation may act as an

Figure 2. Dependence of $\log k_{et}$ on ΔG°_{et} for electron transfer reactions with different λ based on Eq. 1 [64–66].

efficient catalyst to accelerate the rates of electron transfer. The radical anions $A^{\bullet-}$ may be stabilized by the interaction with acids, while the radical cations $D^{\bullet+}$ may have a strong interaction with bases. The stronger the interaction of **C** (acid or base) with the radical anions or cations, the faster are the rates of electron transfer, as the free energy change of electron transfer decreases. This means that an electron is transferred instantaneously according to the Franck–Condon principle when the reactant pair is activated by the interaction with **C** to reach the nuclear configurations where the energy before and after the electron transfer is the same. Once an electron has been transferred, the interaction of **C** with the radical anions (or cations) becomes much stronger to give the thermodynamically more stable products as shown in Scheme 2.

It should be emphasized that there is no need to have an interaction of **C** with **A** and that the interaction with the reduced state ($A^{\bullet-}$) is sufficient to accelerate the rate of electron transfer. This contrasts well with the catalysis on conventional ionic or concerted reactions, in which the catalyst needs to interact with a reactant to accelerate the rate of reactions. In other words the strength of binding of catalyst (**C**) with an electron donor (**D**) or acceptor (**A**) is altered drastically depending on the redox state, as shown in Scheme 3. Even if there is no interaction between **D** (or **A**) and **C**, there can be a strong interaction between $D^{\bullet+}$ (or $A^{\bullet-}$) and **C**. As mentioned above, strong binding is expected between $A^{\bullet-}$ and an acid or between $D^{\bullet+}$ and a base, while there must be much less interaction between **A** and an acid or between **D** and a base. Thus, an acid can catalyze the electron transfer reduction of **A**, while a base can catalyze the electron transfer oxidation of **D**.

Much weaker intermolecular interactions such as hydrogen bonding and π stacking can also be altered depending on the redox state of **D** or **A** [72]. Generally, the gain or loss of an electron by a host (or guest) molecule modifies its charge and electronic distribution and often leads to very significant changes in the strength and

Scheme 3.

nature of the intermolecular forces between the host and guest molecules and their recognition patterns [73]. In such a case, the host (or guest) molecule can act as a catalyst (C in Scheme 3) to control the electron transfer reactions of the guest (or host) molecule. The effects of various molecular recognition elements on the redox behavior and physical properties of redox-active organic molecules including biological systems are discussed in another chapter in this Part [74].

1.3 Acid Catalysis in Electron Transfer

1.3.1 Catalysis of Brønsted Acid

The simplest substance which can act as a catalyst in the electron transfer reduction of an electron acceptor may be a proton ($C = H^+$), since the radical anion of an electron acceptor ($A^{•-}$) becomes a much stronger base as compared with the neutral form (A). The substrates first described here are *p*-benzoquinone derivatives (Q), since the redox and acid–base properties of Q and the reduced forms ($Q^{•-}$ and Q^{2-} as the one-electron and two-electron reduced form, respectively) have well been established and they exhibit important thermodynamic parameters in biological redox systems [75, 76]. The variations of the reduction potentials with pH are governed by the acid–base properties of the reduced species. Semiquinone radical anion ($Q^{•-}$) is not only singly protonated but also doubly protonated, as shown in Eqs. 2 and 3 [75, 76].

In such a case the one-electron reduction potential of Q (E_{red}) is shifted in the positive direction by the protonation of $\text{Q}^{\bullet-}$, according to Eq. 4:

$$E_{\text{red}} = E_{\text{red}}^{\circ} + (2.3RT/F) \log(1 + K_{a1}^{-1}[\text{H}^+] + K_{a1}^{-1}K_{a2}^{-1}[\text{H}^+]^2) \quad (4)$$

where K_{a1} and K_{a2} are the acid dissociation constants of QH^{\bullet} and $\text{QH}_2^{\bullet+}$, respectively. At high pH values ($\text{pH} > \text{p}K_{a1}$), $\text{Q}^{\bullet-}$ predominates as the one-electron reduced species, and thereby E_{red} is independent of pH, being equal to E_{red}° . In the region $\text{p}K_{a2} < \text{pH} < \text{p}K_{a1}$, QH^{\bullet} predominates as the reduced species when the E_{red} value is shifted to the positive direction with the slope of $2.3RT/F$ (F is the Faraday constant) which corresponds to 0.0592 at 298 K. Under more acidic conditions such that $\text{pH} < \text{p}K_{a2}$, the slope would be twice $2.3RT/F$ (0.118 at 298 K).

If one assumes that H^+ has no effect on the one-electron oxidation potential of an electron donor (D), the free energy change of electron transfer from D to Q in the presence of H^+ (ΔG_{et}) can be expressed by Eq. 5:

$$\Delta G_{\text{et}} = \Delta G_{\text{et}}^{\circ} - (2.3RT) \log(1 + K_{a1}^{-1}[\text{H}^+] + K_{a1}^{-1}K_{a2}^{-1}[\text{H}^+]^2) \quad (5)$$

where $\Delta G_{\text{et}}^{\circ}$ is the free energy change in the absence of H^+ . Thus, electron transfer from D to Q becomes more favorable energetically with an increase in the H^+ concentration. If such a change in the energetics is directly reflected in the transition state of electron transfer, the dependence of the rate constant of H^+ -catalyzed electron transfer (k_{et}) on $[\text{H}^+]$ may be given by Eq. 6:

$$k_{\text{et}} = k_{\text{et}}^{\circ}(1 + K_{a1}^{-1}[\text{H}^+] + K_{a1}^{-1}K_{a2}^{-1}[\text{H}^+]^2) \quad (6)$$

where k_{et}° is the rate constant in the absence of H^+ . Thus, the dependence of the rate constant (k_{et}) of H^+ -catalyzed electron transfer on $[\text{H}^+]$ is expected to change from zeroth order with respect to $[\text{H}^+]$ (independent of $[\text{H}^+]$) when $[\text{H}^+] \ll K_{a1}$ to first order with increasing $[\text{H}^+]$ when $[\text{H}^+] \gg K_{a1}$, and then to second order under more acidic conditions such that $[\text{H}^+] \gg K_{a2}$.

The dependence of k_{et} on $[\text{H}^+]$ in Eq. 6 has been reported for H^+ -catalyzed electron transfer from *cis*-dialkylcobalt(III) complexes (*cis*- $[\text{R}_2\text{Co}(\text{bpy})_2]^+$; R = Me, Et, PhCH_2 ; bpy = 2,2'-bipyridine) to Q as shown in Figure 3 [77]. The acid-catalyzed electron transfer from *cis*- $[\text{R}_2\text{Co}(\text{bpy})_2]^+$ to Q generates *cis*- $[\text{R}_2\text{Co}(\text{bpy})_2]^{2+}$ in which facile cleavage of a pair of cobalt-carbon bonds occurs to give R-R as shown in Scheme 4 [78, 79]. When a relatively strong oxidant such as 2,6- or 2,5-dichloro-*p*-benzoquinone is employed in the electron transfer oxidation of *cis*- $[\text{Et}_2\text{Co}(\text{bpy})_2]^+$, the k_{et} value is constant, independent of pH at high pH, $\text{pH} > \text{p}K_{a1}$

Figure 3. pH dependence of k_{et} for the electron transfer from $cis-[Et_2Co(bpy)_2]^+$ to p -benzoquinone derivatives in $H_2O-EtOH$ (5:1 v/v) at 298 K: 2,6-dichloro- p -benzoquinone (\circ); 2,5-dichloro- p -benzoquinone (\bullet); chloro- p -benzoquinone (\triangle); p -benzoquinone (\blacktriangle); methyl- p -benzoquinone (\square); and 2,6-dimethyl- p -benzoquinone (\blacksquare).

$cis-[R_2Co(bpy)_2]^+$

Scheme 4.

[77]. The acid catalysis starts to operate under acidic conditions, $pH < pK_{a1}$ (Figure 3) [77]. Under more acidic conditions such that $pH < pK_{a2}$, the slope changes from -1 to -2 , showing the second-order dependence of k_{et} on $[H^+]$, agreeing with the expectation based on Eq. 6 [77]. The pK_{a1} and pK_{a2} values of each p -benzoquinone derivative determined from the pH dependence of k_{et} in Figure 3 agree well with the known values in the literature [75, 77]. Thus, the acceleration of the rate of electron transfer is achieved by the protonation of $Q^{\cdot-}$ in Eqs. 2 and 3, and the number of protons which can form the chemical bond with $Q^{\cdot-}$ determines the kinetic order

Scheme 5.

(zeroth, first or second order) with respect to the acid concentration. It should be noted that no protonation of Q occurs in the pH region in Figure 3 [77].

Acid catalysis is also effective for the electron transfer reduction of flavins, which are also important coenzymes in the biological redox reactions [80–82]. Flavin analogues (FI: **1a** and **1b**) are known to be protonated at the N-1 position in a strongly acidic aqueous solution as shown in Scheme 5 ($\text{p}K_{\text{a}} \approx 0$) [83]. In an aprotic solvent such as acetonitrile (MeCN), the protonation of FI occurs much more readily than in H_2O [84]. The one-electron reduced radical FIH^* can also be protonated to give FIH_2^{*+} in acetonitrile (Scheme 5) [84]. In such a case, an acid-catalyzed electron transfer from $\text{cis-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ to FIH^+ in MeCN occurs to yield FIH_2^{*+} (Eq. 7) [84]:

The selective formation of FIH_2^{*+} is well characterized by the ESR spectra [84]. No reaction occurs without acid [84]. Since FI is already protonated at the oxidized state in the presence of HClO_4 in MeCN, the rate constant of electron transfer (k_{et}) from $\text{cis-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ to FIH^+ increases linearly with $[\text{H}^+]$ [84], in contrast to the case of the acid-catalyzed reduction of Q, in which the k_{et} value shows the second-order dependence with respect to $[\text{H}^+]$ when QH^* is further protonated to give QH_2^{*+} [77].

According to Eq. 6, the k_{et} value becomes larger with decrease in K_{a} , i.e., the larger $\text{p}K_{\text{a}}$ value. In general, the $\text{p}K_{\text{a}}$ value becomes larger in an aprotic solvent such as MeCN as compared with the value in water, since the solvation energy for proton in an aprotic solvent is much less than that in water [85]. Thus, acid catalysis in electron transfer reactions is expected to be much more efficient in acetonitrile than in water. In fact, the luminescence of $[\text{Ru}(\text{bpy})_3]^{2+*}$ (* denotes the excited state) is quenched by electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to acetophenone in the

Figure 4. Plots of $\log k_{\text{et}}$ for photoinduced electron transfer reactions from $[\text{Ru}(\text{bpy})_3]^{2+}$ to nitrobenzene derivatives (Nos. 1–16) in the absence of HClO_4 and acetophenone derivatives (Nos. 17–21) in the presence of HClO_4 (0.10 mol dm^{-3}) in MeCN vs. the free energy change of electron transfer, $\Delta G^\circ_{\text{et}}$ {= the difference between the one-electron redox potentials of $[\text{Ru}(\text{bpy})_3]^{2+}$ and the electron acceptors in the absence of HClO_4 in MeCN, $E^\circ_{\text{ox}} - E^\circ_{\text{red}}$ } [77].

presence of HClO_4 in MeCN (Eq. 8):

although no electron transfer occurs in water [77, 86]. The k_{et} value increases linearly with the HClO_4 concentration ($\leq 0.10 \text{ M}$), indicating that the acetophenone radical anion is singly protonated under such experimental conditions as discussed above. The luminescence of $[\text{Ru}(\text{bpy})_3]^{2+}$ is quenched also by other acetophenone derivatives having more negative reduction potentials than acetophenone in the presence of HClO_4 (0.10 M) in acetonitrile at 298 K [77, 86]. Figure 4 shows plots of $\log k_{\text{et}}$ values for photoinduced electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+}$ to nitrobenzene derivatives in the absence of HClO_4 in MeCN [87] and to acetophenone derivatives in the presence of HClO_4 (0.10 M) in MeCN at 298 K vs. the free energy change of electron transfer $\Delta G^\circ_{\text{et}}$ in the absence of HClO_4 [77]. The dependence of $\log k_{\text{et}}$ in the absence of HClO_4 on $\Delta G^\circ_{\text{et}}$ is typical for photoinduced electron transfer; the $\log k_{\text{et}}$ value increases linearly with decreasing $\Delta G^\circ_{\text{et}}$ value with a slope of $-F/(2.3RT)$, which is equal to -16.9 at 298 K , to reach the diffusion-limited value, $2.0 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ [88]. The $\log k_{\text{et}}$ values for acetophenone derivatives in

Scheme 6.

the presence of HClO_4 (0.10 M) are much larger than those extrapolated in the correlation between $\log k_{\text{et}}$ and $\Delta G^{\circ}_{\text{et}}$ (Figure 4). This indicates that the one-electron reduction potentials of acetophenone derivatives are shifted in the positive direction by the presence of HClO_4 due to the protonation of the corresponding radical anions. The positive shifts, ΔE_{red} , of acetophenone derivatives in the presence of HClO_4 (0.10 M) are readily evaluated as the difference in the abscissa between the value on the correlation of $\log k_{\text{et}}$ vs. $\Delta G^{\circ}_{\text{et}}$ and the value in the absence of HClO_4 as shown in Figure 4. The ΔE_{red} value of *p*-methoxyacetophenone in the presence of 0.10 M HClO_4 is as large as 1.19 eV, which corresponds to a *sextillion*-fold (10^{21} !) acceleration of the rate of electron transfer at 298 K.

Remarkable acid catalysis is also observed in thermal electron transfer from mild inorganic one-electron reductants, 1,1'-dimethylferrocene $[\text{Fe}(\text{MeC}_5\text{H}_4)_2]$ (or decamethylferrocene $[\text{Fe}(\text{Me}_5\text{C}_5)_2]$) to a series of α -halo ketones such as phenacyl halides (PhCOCH_2X , $\text{X} = \text{Br}, \text{Cl}$) in the presence of HClO_4 in MeCN at 335 K (Scheme 6) [89]. No reaction takes place in the absence of HClO_4 in MeCN or in the presence of HClO_4 in an aqueous solution [89]. The rate constant of electron transfer (k_{et}) increases linearly with increase in the HClO_4 concentration and thereby the second acid-catalyzed electron transfer from $\text{Fe}(\text{MeC}_5\text{H}_4)_2$ to $\text{PhCO}(\text{H})\text{CH}_2\text{X}^{\bullet}$ to yield $[\text{Fe}(\text{MeC}_5\text{H}_4)_2]^+$, PhCOCH_3 and X^- may be much faster than the initial electron transfer (Scheme 6).

Acid-catalyzed electron transfer plays an important role in reduction of not only carbonyl compounds but also other substrates such as O_2 [90, 91], NO_2^- [92], nitrobenzene derivatives [93, 94], nitrosobenzene derivatives [93, 94] and sulfoxides [95, 96]. The k_{et} value for the photoinduced electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to nitrobenzene increases parabolically with increase in $[\text{HClO}_4]$ [94]. This indicates that $\text{PhNO}_2^{\bullet-}$ is doubly protonated in the photoinduced electron transfer reaction to give $\text{PhNO}_2\text{H}_2^{+\bullet}$ (Eq. 9):

Figure 5. Dependence of the electron transfer rate constant (k_{et}) on $[\text{HClO}_4]$ for photoinduced electron transfer from AcrH_2 to $[\text{Ru}(\text{bpy})_3]^{2+*}$ in the presence of HClO_4 in MeCN at 298 K [102].

1.3.2 Deceleration and Acceleration Effects of Brønsted Acid

As described above, the protonation of radical anions of electron acceptors produced in thermal and photoinduced electron transfer reactions results in acceleration of the rate of electron transfer as given in Eq. 6, since the electron acceptor ability of electron acceptors is enhanced by the protonation. Conversely, the protonation of electron donors should result in deceleration of the rate of electron transfer, since the donor ability of electron donors is diminished by the protonation. No protonation of metal complexes such as ferrocene derivatives and $[\text{Ru}(\text{bpy})_3]^{2+*}$ used as electron donors occurs in the presence of HClO_4 in MeCN. In contrast to these metal complexes, strong organic electron donors can also be strong bases. For example, analogues of NADH (dihyronicotinamide adenine dinucleotide), which plays a vital role as an electron source in the biological redox reactions [97], are known to be readily protonated in the presence of acid [98–101]. Thus, the rate of photoinduced electron transfer from 9,10-dihydro-10-methylacridine (AcrH_2) to $[\text{Ru}(\text{bpy})_3]^{2+*}$ is decelerated with increasing the HClO_4 concentration as shown in Figure 5 [102]. The inhibitory effect of HClO_4 is ascribed to the protonation of AcrH_2 by which the electron donor ability of AcrH_2 is decreased significantly compared with that of unprotonated AcrH_2 . In such a case, only the unprotonated AcrH_2 can undergo photoinduced electron transfer to $[\text{Ru}(\text{bpy})_3]^{2+*}$ (Scheme 7) and the observed k_{et} value decreases as the concentration of unprotonated AcrH_2 decreases with increasing $[\text{HClO}_4]$.

On the other hand, photoinduced electron transfer from $[\text{Ru}(\text{bpy})_3]^{2+*}$ to PhCOCH_2X is accelerated in the presence of HClO_4 in MeCN as is the case of thermal electron transfer from $[\text{Fe}(\text{MeC}_5\text{H}_4)_2]$ to PhCOCH_2X (Scheme 6).

Scheme 7.

Thus, the $[\text{Ru}(\text{bpy})_3]^{2+}$ -catalyzed photoreduction of PhCOCH_2X by AcrH_2 (Eq. 10)

is initiated by the reductive quenching of $[\text{Ru}(\text{bpy})_3]^{2+*}$ by AcrH_2 in the absence of HClO_4 , while the quenching mechanism is changed to the acid-catalyzed oxidative quenching of $[\text{Ru}(\text{bpy})_3]^{2+*}$ by PhCOCH_2X in the presence of high concentrations of HClO_4 when the reductive quenching is inhibited [102]. The reductive quenching of $[\text{Ru}(\text{bpy})_3]^{2+*}$ by AcrH_2 gives $\text{AcrH}_2^{\bullet+}$ and $[\text{Ru}(\text{bpy})_3]^+$, followed by electron transfer from $[\text{Ru}(\text{bpy})_3]^+$ to PhCOCH_2X to yield $\text{PhCOCH}_2\text{X}^{\bullet-}$ accompanied by regeneration of $[\text{Ru}(\text{bpy})_3]^{2+}$. The acid-catalyzed oxidative quenching of $[\text{Ru}(\text{bpy})_3]^{2+*}$ by PhCOCH_2X gives $[\text{Ru}(\text{bpy})_3]^{3+}$ and $\text{PhC}(\text{OH})\text{CH}_2\text{X}^{\bullet}$, followed by electron transfer from AcrH_2 to $[\text{Ru}(\text{bpy})_3]^{3+}$ to yield $\text{AcrH}_2^{\bullet+}$ accompanied by regeneration of $[\text{Ru}(\text{bpy})_3]^{2+}$. In both cases, net electron transfer from AcrH_2 to PhCOCH_2X is attained and the subsequent electron transfer from $\text{AcrH}_2^{\bullet+}$, which is formed by the deprotonation of $\text{AcrH}_2^{\bullet+}$, to $\text{PhCOCH}_2\text{X}^{\bullet-}$ (or $\text{PhC}(\text{OH})\text{CH}_2\text{X}^{\bullet}$) yields the final product in Eq. 10 [102]. Direct UV irradiation of the absorption band due to AcrH_2 ($\lambda_{\text{max}} = 285 \text{ nm}$) in the presence of phenacyl halides (PhCOCH_2X) also results in photoinduced electron transfer from the singlet excited state of AcrH_2 to PhCOCH_2X , leading to the same products as obtained by the $[\text{Ru}(\text{bpy})_3]^{2+}$ -catalyzed photochemical reaction (Eq. 10) [103, 104].

1.3.3 Catalysis of Metal Ions

Metal ion complexes with radical anions

Brønsted acid catalysis in electron transfer reactions can also be applied to catalysis of metal ions in electron transfer reactions, since not only protons but also metal

ions (M^{n+}) which can act as Lewis acids are able to form strong bond with radical anions. It is certainly desired to detect such radical anion–metal ion complexes. The complex formation between radical anions and metal ions has been known for a long time, since metal ion complexes of ketyls or radical anions of ketones can be readily produced by the one-electron reduction of ketones by reducing with metals [105, 106]. These radical anion–metal ion complexes have been utilized as key intermediates in a variety of organic reactions [107–115]. Although there have been a number of reports on the spectroscopic detection of metal ketyl species in situ [116–121], the high reactivity of the radical anion–metal ion complexes had precluded the isolation and structural determination.

The use of a sterically demanding samarium(II) reducing agent, $\text{Sm}(\text{OAr})_2(\text{THF})_3$ ($\text{Ar} = \text{C}_6\text{H}_2-2,6-t\text{-Bu}_2-4\text{-Me}$) and a highly conjugated aromatic ketone such as fluorenone can sufficiently stabilize the radical anion–metal ion complex with hexamethylphosphoric triamide (HMPA), which was isolated and structurally characterized by X-ray analysis [122]. This complex possesses a distorted trigonal bipyramidal structure with one fluorenone ketyl and two ArO ligands at the equatorial and two THF ligands at the apical positions (Scheme 8). When the fluorenone radical anion– Sm^{3+} complex is dissolved in hexane–diethyl ether, the two THF ligands are substituted by one molecule of Et_2O , and the radical anion complex dimerizes into a pinacolate (Scheme 8) [123]. The newly formed C–C bond in the

Scheme 8.

pinacolate, which is unusually long [1.613(9) Å], can be readily cleaved to regenerate the fluorenone radical anion–Sm³⁺ complex quantitatively (Scheme 8), and thereby the pinacol coupling process is completely reversible [123]. The THF ligand in the fluorenone radical anion–Sm³⁺ complex can be readily replaced by HMPA and the HMPA coordinated complex is stable against ether or hexane (Scheme 8) [123, 124]. The use of HMPA as a stabilizing ligand has been applied to isolate Na⁺ and Ca²⁺ complexes of fluorenone and benzophenone radical anions [123, 125, 126]. Similarly, a series of lanthanide ion (Sm³⁺ and Yb³⁺) complexes with benzophenone and fluorenone radical anions have been isolated and characterized [127]. Sm³⁺ complexes of 2,6-di-*t*-butylsemiquinone and azobenzene radical anions have also been isolated and structurally characterized [128–130]. Transition metal complexes of fluorenone radical anion are reported to be prepared via metathesis reactions of the corresponding alkali-metal complexes with transition metal chlorides as well as via deprotonation of pinacols with a transition metal base [131].

Metal ion catalysis in electron transfer by complexation with radical anions

A relation between complexation of metal ions with radical anions of electron acceptors and the metal ion catalysis in electron transfer reduction of electron acceptors was first clarified for the Mg²⁺ complex of semiquinone radical anions (see below) [132]. Although no electron transfer occurs from decamethylferrocene [Fe(Me₅C₅)₂] to *p*-benzoquinone (Q) in MeCN, the electron transfer is complete upon mixing [Fe(Me₅C₅)₂] and Q in the presence of Mg(ClO₄)₂. The transient electronic spectra of semiquinone radical anion in the presence of different concentrations of Mg(ClO₄)₂ are obtained by measuring the change in initial absorbance at various wavelengths with use of a stopped-flow spectrophotometer as shown in Figure 6 [132]. The transient absorption spectrum of Q^{•−} in the presence of 1.0 × 10^{−2} M Mg²⁺ (λ_{max} = 590 nm) is significantly red-shifted compared with that in the absence of Mg²⁺ (λ_{max} = 422 nm) [133]. Further addition of Mg²⁺ results in a blue shift to λ_{max} = 415 nm with a clean isosbestic point. Such spectroscopic changes clearly indicate the formation of complexes between Q^{•−} and Mg²⁺, which requires two steps. The first step is the formation of a 1:1 complex (Q^{•−}–Mg²⁺) and the second step is an additional addition of Mg²⁺ to form a 1:2 complex (Q^{•−}–2Mg²⁺), as shown in Eqs. 11 and 12:

Transient electronic spectra of the 1:1 and 1:2 complexes are also observed in the electron transfer reduction of 2,5-dichloro-*p*-benzoquinone and 2,5-dimethyl-*p*-benzoquinone [132]. Although the formation constant K_1 for the 1:1 complex is too large to be determined, the formation constant K_2 for the 1:2 complex can be determined as 4.5 M^{−1} and the K_2 value decreases with a decrease in the electron-donating ability of X-substituted semiquinone radical anion (X = 2,5-Me₂ > H > 2,5-Cl₂) [132]. Thus, Mg²⁺ acts as a Lewis acid which can bind with the radical anion base, although the radical anion–Mg²⁺ complexes are unstable owing to the facile disproportionation [132]. The formation of such complexes is also confirmed

Figure 6. Transient absorption spectra of semiquinone radical anion formed in electron transfer reduction of *p*-benzoquinone (Q : 2.4×10^{-4} M) by $[Fe(Me_5C_5)_2]$ (2.4×10^{-3} M) in the presence of $Mg(ClO_4)_2$ [1.0×10^{-2} M (○), 2.0×10^{-1} M (◐)] and by $[Fe(MeC_5H_4)_2]$ (2.4×10^{-3} M) in the presence of $Mg(ClO_4)_2$ [1.6 M (●)] in deaerated MeCN at 198 K [132]. The solid line spectrum without symbols shows the absorption spectrum of $Q^{\bullet-}$ in the absence of $Mg(ClO_4)_2$, prepared by the reaction of Q (2.4×10^{-4} M) with $Me_4N^+OH^-$ (2.4×10^{-4} M) in deaerated MeCN at 298 K [132].

by the ESR spectra observed in the electron transfer reaction from $Fe(MeC_5H_4)_2$ to Q in the presence of Mg^{2+} in deaerated MeCN by applying a rapid-mixing ESR technique [132]. The g value of the $Q^{\bullet-}-2Mg^{2+}$ complex (2.0043) is appreciably smaller than that of free $Q^{\bullet-}$ because of the decrease in the spin density on the oxygen atom in the Mg^{2+} complex [132]. The strong binding between $Q^{\bullet-}$ and Mg^{2+} makes it possible to reduce Q by a weak electron donor which would otherwise have no ability to reduce Q .

Thus, an efficient electron transfer from (TPP)Co (TPP = tetraphenylporphyrin dianion) to Q occurs in the presence of $Mg(ClO_4)_2$ in MeCN at 298 K to yield $[(TPP)Co]^+$ (Eq. 13):

although no electron transfer from (TPP)Co to Q occurs without the metal ion [132]. The electron transfer rates obeyed second-order kinetics, showing a first-order dependence on each reactant concentration. The observed rate constant of electron transfer (k_{et}) increases with increase in $[Mg^{2+}]$ to exhibit a first-order dependence on $[Mg^{2+}]$ at low concentrations, changing to a second-order dependence at high concentrations as shown in Figure 7. Such a dependence of k_{et} on $[Mg^{2+}]$ in Figure 7 is essentially the same as the pH dependence of k_{et} for electron transfer from *cis*-

Figure 7. Dependence of k_{et} and k_{obs} on $[\text{Mg}(\text{ClO}_4)_2]$ for (a) electron transfer from $(\text{TPP})\text{Co}$ ($1.0 \times 10^{-5} \text{ M}$) to p -benzoquinone ($3.7 \times 10^{-3} \text{ M}$) and (b) Diels-Alder reaction of 9,10-dimethylantracene ($1.3 \times 10^{-3} \text{ M}$) with p -benzoquinone ($3.6 \times 10^{-1} \text{ M}$) in the presence of $\text{Mg}(\text{ClO}_4)_2$ in deaerated MeCN at 298 K, respectively [132].

$[\text{Et}_2\text{Co}(\text{bpy})_2]^+$ to Q (Scheme 4) in Figure 3, where the first-order dependence of k_{et} with respect to $[\text{H}^+]$ in the region of $\text{pH} < \text{p}K_{\text{a}1}$ (the slope being -1 for the plot of $\log k_{\text{et}}$ vs. pH) changes to a second-order dependence (the slope being -2) in the region of $\text{pH} < \text{p}K_{\text{a}2}$ [77]. Thus, Eq. (6) is rewritten as:

$$k_{\text{et}} = k^{\circ}_{\text{et}}(1 + K_1[\text{Mg}^{2+}] + K_1K_2[\text{Mg}^{2+}]^2) \quad (14)$$

the validity of which was confirmed by the linear plot of $k_{\text{et}}/[\text{Mg}^{2+}]$ vs. $[\text{Mg}^{2+}]$ for the data in Figure 7 ($k^{\circ}_{\text{et}} = 0$) [132]. From the slope and intercept the K_2 value (4.1 M^{-1}) is obtained, which agrees well with that (4.5 M^{-1}) determined directly from the spectral change of $\text{Q}^{\cdot-}$ in the presence of Mg^{2+} (Figure 6) [132]. The K_2 values for substituted semiquinone radical anions can also be determined from the dependence of k_{et} on $[\text{Mg}(\text{ClO}_4)_2]$ and they also agree with those determined from direct spectroscopic detection of 1:2 complexes between substituted semiquinone radical anions and Mg^{2+} [132]. Such agreements for each quinone indicate that the catalysis of the metal ion is ascribed to the 1:1 and 1:2 complex formation between semiquinone radical anions and the metal ion, which causes a positive shift of the one-electron reduction potential of the quinone. It should be noted that there is little interaction between Q and Mg^{2+} . As described earlier, there is no need to have an interaction between Q and Mg^{2+} and the interaction with the reduced state ($\text{Q}^{\cdot-}$) is essential to accelerate the rate of electron transfer.

Electron transfer from $\text{cis-}[\text{R}_2\text{Co}(\text{bpy})_2]^+$ to Q also occurs efficiently in the presence of Mg^{2+} in MeCN, although no electron transfer occurs in the absence of Mg^{2+} [134, 135]. The observed rate constant of electron transfer (k_{et}) also exhibits a first-order dependence on $[\text{Mg}^{2+}]$ at low concentrations, changing to a second-order dependence at high concentrations [135]. The rate of electron transfer is further increased by the presence of both $\text{Mg}(\text{ClO}_4)_2$ and HClO_4 . Thus, the k_{et} value for electron transfer from $\text{cis-}[\text{Et}_2\text{Co}(\text{bpy})_2]^+$ to Q in the presence of $\text{Mg}(\text{ClO}_4)_2$

(1.0 M) and HClO_4 (0.10 M) in MeCN at 298 K is $5.2 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$, which is 5.2×10^{16} times faster than the rate constant without $\text{Mg}(\text{ClO}_4)_2$ or HClO_4 ($1.0 \times 10^{-14} \text{ M}^{-1} \text{ s}^{-1}$) which is estimated from the correlation between $\log k_{\text{et}}$ and E°_{red} of the oxidants [135]. Various metal ions, in particular rare earth metal ions such as scandium ion, have also been reported to act as very efficient catalysts in the electron transfer reduction of Q by complexation with $\text{Q}^{\bullet-}$ [136].

Mg^{2+} is also effective for electron transfer reduction of O_2 in acetonitrile [137]. Efficient electron transfer from $\text{Fe}(\text{Me}_5\text{C}_5)_2$ to O_2 occurs in the presence of $\text{Mg}(\text{ClO}_4)_2$ in MeCN at 298 K to yield $[\text{Fe}(\text{Me}_5\text{C}_5)_2]^+$ (Eq. 15):

although no electron transfer occurs from $[\text{Fe}(\text{Me}_5\text{C}_5)_2]$ to O_2 in the absence of Mg^{2+} under otherwise the same experimental conditions [137]. As observed in the Mg^{2+} -catalyzed electron transfer from (TPP)Co to Q in Figure 7a, the observed pseudo-first-order rate constant of electron transfer (k_{et}) in an O_2 -saturated MeCN solution exhibits a first- and second-order dependence on $[\text{Mg}^{2+}]$ at low and high Mg^{2+} concentrations, respectively. This indicates that $\text{O}_2^{\bullet-}$ forms complexes with Mg^{2+} with 1:1 and 1:2 stoichiometries at low and high Mg^{2+} concentrations (Eqs. 16 and 17), respectively:

From the linear plot of $(k_{\text{et}} - k_0)/[\text{Mg}^{2+}]$ vs. $[\text{Mg}^{2+}]$ based on Eq. 14 the K_2 value (3.2 M^{-1}) is obtained for the 1:2 complex between $\text{O}_2^{\bullet-}$ and Mg^{2+} [137].

Other metal ions such as Sc^{3+} can also form complexes with $\text{O}_2^{\bullet-}$ [138]. $\text{O}_2^{\bullet-}$ can be produced by photoinduced electron transfer from the excited state of dimeric 1-benzyl-1,4-dihydronicotinamide $[(\text{BNA})_2]$, which can act as a unique two-electron donor [139, 140], to O_2 in propionitrile at low temperatures (e.g. -30°C) [138]. Addition of scandium triflate $[\text{Sc}(\text{OTf})_3]$ to the $(\text{BNA})_2\text{-O}_2$ system results in the appearance of the sharp isotropic ESR signal under irradiation of the light in fluid solution at -30°C as shown in Figure 8 [138]. The clear eight-line *isotropic* spectrum is ascribed to the superhyperfine coupling of $\text{O}_2^{\bullet-}$ with the 7/2 nuclear spin of the scandium nucleus ($a_{\text{Sc}} = 4.26 \text{ G}$). The isotropic g value (2.0163) is appreciably smaller than the average value (2.030) [141] of the principal three g components of $\text{O}_2^{\bullet-}$ at 77 K, being consistent with the spin delocalization to the scandium nucleus as demonstrated by observation of superhyperfine. The $\text{O}_2^{\bullet-}\text{-Sc}^{3+}$ complex is fairly stable at -30°C but the signal intensity decreases with increase in temperature because of the faster disproportionation of the $\text{O}_2^{\bullet-}$ complex [138]. This is the first definitive detection of a $\text{O}_2^{\bullet-}$ -metal ion complex which is responsible for catalysis of metal ions in electron transfer reduction of oxygen.

The $\text{O}_2^{\bullet-}\text{-Sc}^{3+}$ complex can be stabilized by complexation with 3 equiv. of HMPA ligand as reported for the case of the fluorenone radical anion- Sm^{3+}

Figure 8. ESR spectrum observed during irradiation of an oxygen-saturated propionitrile solution containing $(\text{BNA})_2$ (1.7×10^{-3} M) and $\text{Sc}(\text{OTf})_3$ (2.7×10^{-2} M) with a high-pressure mercury lamp at -30°C [138].

complex [123, 124]. The ESR spectrum of the $\text{O}_2^{\bullet-}-\text{Sc}^{3+}-\text{HMPA}$ complex can be detected even at 60°C [138]. The g value increases with decrease in temperature from 2.0163 (60°C) to 2.0168 (-30°C), when the a_{Sc} value decreases from 3.88 G (60°C) to 3.77 G (-30°C). Such change in the g and a_{Sc} values with temperature may be attributed to the stronger coordination of HMPA to Sc^{3+} , which results in weaker coordination of $\text{O}_2^{\bullet-}$ to Sc^{3+} at lower temperature. The weaker the coordination of $\text{O}_2^{\bullet-}$ to Sc^{3+} , the closer to free $\text{O}_2^{\bullet-}$, and then the larger is the g value but the smaller is the a_{Sc} value.

Oxygen enriched in ^{17}O gave the ESR spectrum of the $\text{O}_2^{\bullet-}-\text{Sc}^{3+}-\text{HMPA}$ complex with ^{17}O enriched oxygen, for which two inequivalent $a(^{17}\text{O})$ values (21 and 14 G) were obtained [138]. Such inequivalent $a(^{17}\text{O})$ values are fully consistent with an ‘end-on’ coordination form of $^{\bullet}\text{O}-\text{O}^--\text{Sc}^{3+}(\text{HMPA})$ in which the electron spin is more localized at the terminal oxygen. The unrestricted Hartree-Fock (UHF) SCF optimization using the 6-311++G** basis set also supports an ‘end-on’ coordination form of $^{\bullet}\text{O}-\text{O}^--\text{Sc}^{3+}$ [138]. Such an ‘end-on’ coordination of $\text{O}_2^{\bullet-}$ to Sc^{3+} results in the removal of degeneracy of the SOMO (singly occupied molecular orbital) orbital, decreasing the relaxation time significantly to make it possible to observe the ESR spectrum in fluid solution at temperatures even higher than room temperature. When $\text{O}_2^{\bullet-}$ is adsorbed on solid surfaces, both side-on and end-on coordinations have been reported depending on the metal oxide [142–145].

Metal ion catalysis in electron transfer reduction of radicals and radical anions

Metal ions can also drastically accelerate the electron transfer reduction of nitroxide and nitrogen centered radicals [146]. Electron transfer from 10,10'-dimethyl-9,9',10,10'-tetrahydro-9,9'-biacridine $[(\text{AcrH})_2]$, which can act as an organic electron donor [147, 148], to 2,3-dihydro-3-oxo-2,2-diphenyl-1*H*-indol-1-yloxy radical (RNO^{\bullet}) occurs efficiently in the presence of $\text{Mg}(\text{ClO}_4)_2$ in MeCN at 298 K (Eq. 18):

although no electron transfer occurs without Mg(ClO₄)₂ under otherwise the same experimental conditions. The k_{et} value increases linearly with an increase in [Mg²⁺], indicating 1:1 complex formation between the resulting RNO⁻ and Mg²⁺, since no interaction between Mg²⁺ and the RNO[•] radical has been detected in the electronic spectra in the presence of Mg²⁺ [146]. Similarly, electron transfer from (AcrH)₂ to 1,1-diphenyl-2-picrylhydrazyl (DPPH[•]) occurs efficiently in the presence of Mg²⁺ (Eq. 19):

and the k_{et} value also increases linearly with an increase in [Mg²⁺] [146].

Metal ions also play an essential role in controlling the reactivity of protein radicals through coordination in several biologically important redox processes [149]. Galactose oxidase (GAO, EC 1.1.3.9) is one of the best characterized examples of such systems, where a tyrosyl radical directly coordinated to Cu(II) center is involved as the active species in the aerobic oxidation of D-galactose and primary alcohols to the corresponding aldehydes [150–153]. The crystal structure of galactose oxidase at 1.7 Å resolution has clearly shown that the tyrosine residue (Tyr 272, the precursor of the tyrosyl radical) is covalently bound to the sulfur atom of the adjacent Cys 228 at the α-position of the phenol ring as illustrated in Scheme 9 [151]. The strong binding of the organic cofactor as the phenolate form to the Cu(II) ion is expected to enhance the oxidizing ability of the phenoxyl radical as compared to the corresponding free radical. The GAO model study has shown that the one-electron reduction potential of a phenoxyl radical ($E^{\circ}_{red} = -0.31$ V vs. SCE) is shifted to a much more positive value ($E^{\circ}_{red} = +0.66$ V vs. SCE) when the corresponding phenolate is bound to the Cu(II) ion in Scheme 9 [154]. It has also been shown that such a synthetic model copper(II) complex of the active form of GAO possesses the alcohol-oxidation ability [155–158].

Compared with the electron transfer reduction of neutral radicals, the reduction of radical anions may be more readily catalyzed by metal ions which have weak Lewis acidity, since the binding to dianions produced in the electron transfer reduction of radical anions should be much stronger than the binding to monoanions. As such, even Na⁺ has been reported to accelerate electron transfer from 1-benzyl-1,4-

Scheme 9.

dihydronicotinamide (BNAH) to *p*-chloranil radical anion ($\text{Cl}_4\text{Q}^{\bullet-}$) in MeCN (Eq. 20) [159]:

The addition of NaClO_4 to the $\text{BNAH}-\text{Cl}_4\text{Q}^{\bullet-}$ system results in an increase in the rate of electron transfer from BNAH to $\text{Cl}_4\text{Q}^{\bullet-}$ where the k_{obs} value increases linearly with increase in $[\text{NaClO}_4]$, whereas no acceleration of the rates is observed by addition of *n*- Bu_4NClO_4 [159]. The significant catalytic effect of Na^+ on the electron transfer from BNAH to $\text{Cl}_4\text{Q}^{\bullet-}$ was also confirmed by a voltammetric study [159]. The reduction peak potential of $\text{Cl}_4\text{Q}^{\bullet-}$ is significantly shifted to the positive direction in the presence of 0.10 M NaClO_4 as compared with the position in the presence of 0.10 M *n*- Bu_4NClO_4 [159]. Such a positive shift in the presence of NaClO_4 indicates that the one-electron reduction of $\text{Cl}_4\text{Q}^{\bullet-}$ is accompanied by complex formation between the dianion (Cl_4Q^{2-}) and Na^+ , since no effect of Na^+ was observed on the electronic spectrum of $\text{Cl}_4\text{Q}^{\bullet-}$ [159]. In fact, the redox couple $\text{Cl}_4\text{Q}/\text{Cl}_4\text{Q}^{\bullet-}$ is unaffected by the presence of 0.10 M NaClO_4 compared with that in the presence of 0.10 M *n*- Bu_4NClO_4 [159]. Other metal ions such as Mg^{2+} , which is a relatively strong Lewis acid compared with Na^+ , can interact with the radical anion (see above), leading to rapid disproportionation of the radical anion [132].

Bimetallic catalysis in electron transfer

The biological catalytic activity of metalloproteins for redox reactions is usually associated with a particular coordination environment of the metal active site [160, 161]. In particular, there has been considerable interest in O_2 -binding and -activation by non-heme metalloenzymes [162–167]. A redox-active metal center is often associated with another metal center which can accelerate the redox process of O_2

in biological systems [160, 161]. A typical example is the copper–zinc superoxide dismutase (Cu,Zn-SOD) which contains an imidazolate-bridged Cu(II)–Zn(II) bimetallic center in its active site [168–171]. This enzyme catalyzes the disproportionation (dismutation) of toxic $\text{O}_2^{\bullet-}$ to O_2 and H_2O_2 [172, 173], thus preventing oxidative damage by the anticancer and antiaging mechanisms [174, 175]. The copper ion is coordinated to four imidazole N atoms of histidine residues in a distorted square-pyramidal geometry while the zinc ion located at a distance of 6.2 Å from the copper ion is coordinated to a carboxylato O atom of an aspartic acid residue and three imidazole N atoms of histidine residues in a distorted tetrahedral structure [168, 169]. A number of SOD model complexes have been designed and synthesized to provide valuable insights into the structure and catalytic function of the Cu,Zn-SOD active site [176–182].
